Diabetic neuropathy may be a consequence of metabolic disturbances in the neurons, microangiopathy affecting the capillary supply to neurons, or an autoimmune process. It affects 60% to 70% of the diabetic population and has a broad spectrum of presentation. Clinically, it most commonly presents as a diffuse symmetric sensorimotor syndrome, as carpal tunnel syndrome, or as autonomic neuropathy (e.g., tachycardia or orthostatic hypotension caused by cardiovascular autonomic neuropathy). Symptomatic diabetic peripheral neuropathy occurs in 25% of patients with diabetes. It is characterized by paresthesia and pain in the lower extremities that may be mild or severe and unrelenting, decreased sensation to monofilament testing, decreased ankle and knee jerks, and decreased nerve conduction velocity. The decreased sensation associated with peripheral neuropathy contributes to the progression of foot injuries and infections that may go unnoticed by the patient until they are severe. The management of diabetic neuropathies has been reviewed.[7,292,293] To view a video of how to perform a complete foot examination, see http://www.medscape.com/viewarticle/708703.

Pharmacologic management consists of symptomatic therapies. Painful neuropathy may respond to simple analgesics (e.g., acetaminophen) or nonsteroidal anti-inflammatory drugs. The analgesic selected should be based on the patient's history of responsiveness to these agents as well as their duration of action and side effect profiles. Side effects include GI upset and bleeding, and renal and hepatic toxicity. Avoid chronic nonsteroidal anti-inflammatory drug use owing to their renal toxicity and development of GI ulcers. Other pharmacologic options include tricyclic antidepressants (TCAs), duloxetine (a serotonin and norepinephrine reuptake inhibitor), gabapentin, pregabalin, and other anticonvulsants (carbamazepine, lamotrigine, topiramate, and oxcarbazepine). Only pregabalin and duloxetine have the FDA indication for the treatment of DPN; others are off label. Efficacy, side effects, drug interactions, renal and hepatic function, and cost should all be considered when an agent is chosen. Often less expensive options are tried first, off label such as gabapentin or a TCA.[294–296]

Topical application of 0.075% capsaicin has been recommended for diabetic neuropathy but may take several weeks to work. Lidocaine 5% patches have also been used. These may be helpful in patients intolerant to oral medications. These may be used in combination with oral medications. Tramadol or opiates may also be used second line.[294–296]

CASE 53-19, QUESTION 3: Can anything be done for H.D.'s peripheral vascular disease?

Peripheral vascular disease or peripheral arterial disease presents as diminished or absent foot pulses, intermittent claudication, skin ulcers, gangrene, or amputation. People with diabetes are 2 to 10 times more likely to experience symptoms of peripheral arterial disease than those without diabetes, and half of all nontraumatic amputations in the United States are performed in patients with diabetes. In one study that followed Type 2 patients for 7 years, 5.5% had an amputation. The prevalence of this condition increases with age, duration of diabetes, and the presence of risk factors such as hypertension or smoking.[293,297]

Signs and symptoms of peripheral arterial disease include leg pain, which is relieved by rest; cold feet; nocturnal leg pain, which is relieved by dangling the feet over the bed or walking; absent pulses; loss of hair on the foot and toes; and gangrene. Treatment of this condition includes elimination and treatment of risk factors such as smoking, dyslipidemia, hypertension, and hyperglycemia; antiplatelet therapy; exercise, which is the mainstay of therapy; and revascularization surgery.[297] H.D. should be thoroughly educated regarding proper foot care, perform daily self-foot examinations, and receive regular care by a podiatrist.[298]

DRUG-INDUCED ALTERATIONS IN GLUCOSE HOMEOSTASIS

Persons with diabetes are likely to take more drugs in their lifetime than any other group of patients. Patients with Type 2 diabetes present with a constellation of chronic conditions, including hypertension, dyslipidemia, and CVD, all of which will likely require drug therapy. Drugs to manage depression, intermittent infections, and neurologic and ophthalmologic conditions also are commonly prescribed. Because we know that the actions of drugs are complex and that for every desired effect there are several other unwanted effects, each time a drug is added to the regimen of someone with diabetes it is important to assess the patient's situation to determine whether a potential exists for a drug–drug or drug–disease interaction or whether the benefit of the newly prescribed drug is likely to outweigh its risks. With the availability of online drug information databases to assist in assessment of drug–drug and drug–disease interactions, a detailed listing of drugs that can exacerbate hyperglycemia and hypoglycemia is not provided. Below, a few case examples are illustrated. Some medications that can have significant hyperglycemic effects include atypical antipsychotics, protease inhibitors, corticosteroids, immunosuppressants (e.g., tacrolimus, cyclosporine), niacin (higher doses), gonadotropin-releasing hormone agonists (used in men for prostate cancer), and pentamidine (can also cause hypoglycemia).[299,300] Patients should be monitored closely for a medication's possible effect on the BG levels.

Drug-Induced Hyperglycemia

CORTICOSTEROIDS

CASE 53-20

QUESTION 1: A.L., a 37-year-old obese woman with systemic lupus erythematosus, has been taking 60 mg/day of prednisone for 6 months. During this period, her weight has increased by 30 lb and she has experienced glycosuria (no ketones). Her primary provider asked her to start SMBG. She was referred to the diabetes clinic, where her predinner and bedtime BG values were found to be 140 to 160 mg/dL and FBG values were 80 to 105 mg/dL. Physical examination shows a 5 feet 2 inch, 150-lb, depressed woman with truncal obesity and an acneiform rash. Her mother and one sister have Type 2 diabetes. How do corticosteroids contribute to diabetes mellitus? How should A.L. be treated?

The term steroid diabetes was first used to describe the hyperglycemia and glycosuria seen in patients with Cushing syndrome. Now, it is associated more commonly with exogenously administered glucocorticoids and has been a side effect of parenteral, oral, and even topical therapy. Corticosteroids are one of the most common drug groups that unmask latent diabetes or aggravate preexisting disease, and they may produce hyperglycemia and overt diabetes in individuals who are not otherwise predisposed.

Corticosteroids increase hepatic gluconeogenesis, suppress insulin secretion, and decrease tissue responsiveness to insulin.[300] The primary effect is impaired glucose disposal after meals, resulting in daytime hyperglycemia, and by morning, the glucose levels normalize. Although steroid-induced diabetes generally is mild and rarely associated with ketonemia, a wide spectrum of severity may be encountered—from asymptomatic, abnormal glucose tolerance tests to difficult-to-control, insulin-requiring disease. The onset of glucose tolerance can occur within hours to days or after months to years of chronic therapy. The effect generally is considered dose-dependent and usually is reversible on discontinuation of the drug.

A.L. exhibits many symptoms that can be attributed to supraphysiologic doses of corticosteroids: truncal obesity, depression, acneiform rash, and diabetes. Mildly elevated glucose levels in obese individuals, as in A.L.'s case, sometimes can be controlled by diet, but may require treatment with a short-acting insulin secretagogue or rapid-acting insulin before meals.[300] A person with diabetes whose BG is increased by use of a glucocorticoid should modify treatment appropriately to restore glycemic control. It is important to anticipate the need to modify insulin or other antidiabetic therapy because corticosteroid doses are increased or decreased.

SYMPATHOMIMETICS

CASE 53-21

QUESTION 1: R.C., a 41-year-old man with Type 1 diabetes, is well controlled on a basal-bolus insulin regimen and has been taking pseudoephedrine 30 mg QID for 7 days and Robitussin DM 10 mL QID (which contains 2.92 g of sugar/5 mL) for a cold. Recently, glucose concentrations have been higher than usual. Can pseudoephedrine or the cough preparation be the cause of his poor glycemic control? Discuss the use of sympathomimetics and cough preparations in patients with diabetes.

Over-the-counter drug products, such as decongestants and diet aids, which contain sympathomimetics, carry warning labels that caution against their use in patients with diabetes. Standard sugar- and ethanol-containing cough preparations also carry such warning labels. However, clinically significant drug-induced glucose intolerance probably is very infrequent. It is well established that parenterally administered epinephrine increases BG concentrations secondary to increased glycogenolysis and gluconeogenesis. Other sympathomimetics generally do not have as potent an effect on BG as epinephrine, and their use usually does not pose a practical problem in diabetic patients. Furthermore, the effects of sympathomimetics on BP must be considered in many patients with diabetes. Therefore, antihistamines or occasional use of nasal sprays for severe congestion may be needed.

In summary, pseudoephedrine or the cough preparation may be aggravating R.C.'s glycemic control, although at these low-to-normal therapeutic doses, it is quite unlikely. The stress related to R.C.'s underlying cold is more likely to be impairing his glucose tolerance than these low doses of sympathomimetic agents or the small amounts of sugar contained in the cough syrup.

p. 1147

Drug-Induced Hypoglycemia

ETHANOL

CASE 53-22

QUESTION 1: C.F., a 22-year-old woman with newly diagnosed Type 1 diabetes, enjoys a glass or two of wine with her evening meal. What effect does alcohol have on a patient with diabetes, particularly one using insulin? Is alcohol contraindicated in C.F. or any person with diabetes?

Clinicians often are reluctant to permit the use of alcoholic beverages in patients with diabetes. However, barring contraindications that are similar in the nondiabetic and diabetic patient alike (e.g., alcoholism, hypertriglyceridemia, gastritis, pancreatitis, pregnancy), a person with diabetes can safely enjoy a moderate alcohol intake as long as certain precautions are taken. For an in-depth discussion, the reader is referred to two comprehensive reviews of alcohol and diabetes,[301,302] parts of which are summarized in the following list:

- Drink in moderation. The ADA defines this as a daily intake of one drink for adult women and two drinks for adult men (one drink is defined as 5 ounces of wine, 12 ounces of beer, or 1.5 ounces of distilled liquor). The patient should be aware of his/her own sensitivity to the intoxicating effects of ethanol and adjust consumption downward, if needed. This is particularly important for insulin-dependent patients. When having a drink, be sure to have it with a carbohydrate-containing meal.
- Avoid drinks that contain large amounts of sugar, such as liqueurs, sweet wines, a sugar-containing mixes. Instead, consider dry wines, light beers, and distilled spirits. Not only does the simple sugar content add an additional source of glucose and calories to the diet, but ethanol ingested with simple sugar-containing mixers enhances reactive hyperglycemia.
- Remember to count the calories in alcohol (calories = [0.8] × [proof] × [ounces]); substitute 1 ounce of alcohol for two fat exchanges.
- Be aware that the symptoms of alcohol intoxication and hypoglycemia are similar. hypoglycemia is mistaken for intoxication by others, appropriate and potentially life-saving treatment can be delayed.
- Be aware of alcohol–sulfonylurea drug interactions, specifically the alcohol-induced enzyme induction of tolbutamide metabolism and the chlorpropamide–alcohol flush reaction.

Eye Disorders

Steven R. Abel and Suellyn J. Sorensen

CORE PRINCIPLES	CHAPTER CASES
GLAUCOMA	
1 There are different types of glaucoma, including open-angle and angle-closure glaucoma. Angle-closure glaucoma is a medical emergency requiring immediate intervention. Open-angle glaucoma is a chronic condition, which can result in progressive loss of vision leading to blindness if left untreated.	**Case 54-1 (Question 1)**
2 Treatment for open-angle glaucoma is targeted toward reducing intraocular pressure (IOP), a clinical measure of drug efficacy. β-Adrenergic blockers, prostaglandin analogs (PGAs), and α-adrenergic agonists are the mainstay of treatment. Treatment is not curative.	**Case 54-1 (Question 2), Figure 54-1, Table 54-1**
OCULAR AND SYSTEMIC SIDE EFFECTS OF DRUGS	
1 Many widely used medications for various conditions cause ocular side effects. The true incidence is frequently not known, making the reporting of ocular side effects of drugs an important function for any healthcare practitioner.	**Case 54-3 (Question 1), Table 54-3**
2 Conversely, many topically administered ocular medications may cause systemic symptoms.	**Case 54-10 (Question 1)**
COMMON OCULAR DISORDERS	
1 Stye(hordeolum) is a common ocular disorder for which no viable over-the-counter treatment exists.	
2 Conjunctivitis (pinkeye) is frequently related to bacterial or viral infection, or allergy. Viral conjunctivitis is generally self-limiting. Bacterial conjunctivitis should be treated with an appropriate antimicrobial, recognizing that Gram-positive organisms are frequently the cause. A number of agents are available for the treatment of allergic conjunctivitis. Among those, decongestants (e.g., tetrahydrozoline) should be used for no more than 72 hours, because they may mask a more serious condition or result in rebound redness.	**Case 54-5 (Question 1)**
CORTICOSTEROIDS	

① Topicalcorticosteroids are used for a variety of ocular inflammatory conditions. The most potent topical corticosteroid is prednisolone acetate 1%.	**Case 54-8 (Question 1), Table 54-4**
② Topical and oral corticosteroids may be associated with serious side effects such as increases in IOP and cataracts (with long-term use).	**Case 54-8 (Question 1), Table 54-5**
AGE-RELATED MACULAR DEGENERATION	
① There are two forms, dry (affecting 85% of patients) and the more serious form, wet (affecting 15% of patients).	**Case 54-13 (Question 1)**
② Wetmacular degeneration is associated with abnormal growth of blood vessels behind the retina (choroidal neovascularization) and may be treated by vascular endothelial growth factor (VEGF) inhibitors.	**Case 54-13 (Question 1)**

The eye is a highly complex organ composed of various parts, all of which must function in integration to permit vision. A brief overview of the anatomy and physiology of the eye prefaces the presentation of specific eye disorders. Readers should consult an ophthalmology textbook for an understanding of ocular anatomy, physiology, and general ophthalmology (e.g., Vaughan and Asbury's General Ophthalmology).[1]

OCULAR ANATOMY AND PHYSIOLOGY

The eyeball is approximately 1 inch wide and is housed in a cavity (i.e., eye socket) formed by two bony orbits that are lined with fat, which serves to protect the eyeball. Six ocular muscles facilitate movement of the eyeball (Fig. 54-1).

The outer coat of the eye is made up of the sclera, conjunctiva, and cornea. The sclera is the white, dense, fibrous protective coating. The episclera, a thin layer of loose connective tissue, contains blood vessels that cover and nourish the sclera. The conjunctiva is a mucous membrane that covers the anterior portion of the eye and lines the eyelids. The cornea is the transparent, avascular tissue that functions as a refractive and protective window membrane through which light rays pass en route to the retina.

The corneal epithelium and endothelium are lipophilic, and the centrally located stroma is hydrophilic. These three corneal layers are particularly important because they affect drug penetration through the cornea. Ophthalmic medications, which are both fat- and water-soluble, are best able to penetrate through the intact cornea.

The iris, choroid, and ciliary body are known collectively as the uveal tract. The iris is a colored, circular membrane suspended between the cornea and the crystalline lens. It controls the amount of light that enters the eye. The choroid, located between the sclera and retina, is largely made up of blood vessels, which nourish the retina. The ciliary body is adherent to the sclera and contains the ciliary muscle and ciliary processes. The ciliary muscle contracts and relaxes the zonular fibers, which hold the crystalline lens in place. The ciliary processes are responsible for the secretion of aqueous humor, a clear liquid that occupies the anterior chamber. The anterior chamber is bounded anteriorly by the cornea and posteriorly by the iris. The posterior chamber lies between the iris and the crystalline lens.

Figure 54-1 Anatomy of the human eye. (Adapted from http://commons.wikimedia.org/wiki/File:Eyesection.svg)

The inner segment of the eye contains the retina with the optic nerve. The retina, the light-sensitive tissue at the back of the eye, contains all of the sensory receptors for light transmission. The optic nerve, a bundle of more than a million nerve fibers, transmits visual impulses from the retina to the brain.

The crystalline lens, aqueous humor, and vitreous humor assist the cornea with the refraction of light. The lens, located behind the iris, functions to focus light onto the retina by changing its shape to accommodate near or distant vision. The innermost part of the lens (i.e., the nucleus) is surrounded by the softer material of the cortex.

The aqueous humor, the thin watery fluid that fills the anterior chamber (i.e., the space between the cornea and the iris) and posterior chamber of the eye, functions to provide nourishment to the cornea and lens. Disorders involving the aqueous humor are presented in the section on glaucoma. The primary function of the vitreous humor (i.e., the jellylike substance between the lens and the retina) is to maintain the shape of the eye and allow the transmission of light to the retina.

The eyelids and eyelashes are the outermost means of protection for the eye. The eyelids contain various sebaceous and sweat glands, which may become infected or inflamed, contributing to many ocular disorders.

The eye is innervated by both the sympathetic and parasympathetic nervous systems. Parasympathetic fibers, originating from the oculomotor nerve in the brain, innervate the ciliary muscle and sphincter pupillae muscle that constrict the pupil. As a result, parasympathomimetic (cholinergic) medications generally are associated with miosis (pupillary contraction), and parasympatholytic (anticholinergic) agents with mydriasis (pupillary dilation) and cycloplegia. The term cycloplegia refers to a paralysis of the ciliary muscle and zonules (fibrous strands connecting the ciliary body to the lens) that results in decreased accommodation (adjustment of the lens curvature for various distances) and blurred vision. Tear secretion by the lacrimal glands also is a parasympathetic function.

Sympathetic fibers from the superior cervical ganglion in the spinal cord innervate the dilator pupillae muscle, the blood vessels of the ciliary body, the episclera, and the extraocular muscles. Sympathomimetics cause mydriasis without affecting accommodation.

In this chapter, we will discuss glaucoma, ocular and systemic side effects of drugs, common ocular disorders, ocular inflammatory conditions, and age-related macular degeneration. These are all common conditions that the pharmacist may encounter in all practices of pharmacy. It is important for the pharmacist to be educated on these disorders and their associated treatment so that the pharmacist can evaluate the appropriateness of pharmacotherapy, screen for adverse effects and drug interactions, and counsel patients on their ocular medications.

GLAUCOMA

Glaucoma is a leading cause of irreversible blindness worldwide. The estimated number of suspected cases worldwide is 60 million, increasing to 76 million in 2020 and 111 million in 2040. In the United States, an estimated 3 million Americans are living with glaucoma but only half know they have it. Glaucoma is a nonspecific term used for a group of diseases that can irreversibly damage the optic nerve, resulting in visual field loss. Increased intraocular pressure (IOP) is the most common risk factor for the development of glaucoma; however, even people with “normal”

IOPs can experience vision loss from glaucoma. Generally, the higher the IOP is, the greater the risk for developing glaucoma. Increasing age, African-American race, family history, thinner central corneas, and larger vertical cup–disc ratios are other risk factors for glaucoma.[1–3]

Intraocular Pressure

The inner pressure of the eye (i.e., IOP) is influenced by the production of aqueous humor by the ciliary processes and the outflow of aqueous humor through the trabecular meshwork. The tonometry test to measure the IOP is based on the pressure required to flatten a small area of the central cornea. Generally, an IOP of 10 to 20 mm Hg is considered normal. An IOP of 22 mm Hg or greater should arouse suspicion of glaucoma, although a more rare form of glaucoma is associated with a low IOP.

Ocular Hypertension

Ocular hypertension has been defined as an IOP exceeding 21 mm Hg, normal visual fields, normal optic discs, open angles, and the absence of any ocular disease contributing to the elevation of IOP. Only a small percentage of patients with ocular hypertension have open-angle glaucoma. An ophthalmoscope can examine the inside of the eye, especially the optic nerve, and a diagnosis of glaucoma can be applied when pathologic cupping of the optic nerve is observed.

Open-Angle Glaucoma

Primary open-angle glaucoma (POAG) occurs in about 1.8% of people older than 40 years of age in the United States; however, glaucoma can affect other age groups, including children.[1–3] In patients with POAG, aqueous humor outflow from the anterior chamber is continuously subnormal primarily because of a degenerative process in the trabecular meshwork. The IOP can vary in the course of a day from normal to significantly high pressures.[1] The decreased outflow appears to be caused by degenerative changes in outflow channels (i.e., the trabecular meshwork and Schlemm canal) and tends to worsen with the passage of time.[1] In rare cases, the outflow is normal even during a phase of elevated IOP, and the elevation appears to be to the result of hypersecretion of aqueous humor.[1]

The onset of POAG usually is gradual and asymptomatic. A defect in the visual field examination may be present in early glaucoma, but loss of peripheral vision usually is not seen until late in the course of the disease. Visual field defects correlate well with changes in the optic disc and help differentiate glaucoma from ocular hypertension in patients with increased IOP. Patients with normal visual fields and an IOP of 24 mm Hg or greater have a 10% likelihood of developing glaucoma in 5 years.[5]

Angle-Closure Glaucoma

Examination of the anterior chamber angle by gonioscopy, using a corneal contact lens, a magnifying device (e.g., a slit-lamp microscope), and a light source, assists in differentiating between open-angle glaucoma and angle-closure glaucoma. Angle-closure glaucoma accounts for approximately 5% to 10% of all primary glaucoma cases. The sole cause of the elevated IOP in angle-closure glaucoma is closure of the anterior chamber angle.[1,5]

Angle-closure glaucoma, which is a medical emergency, usually presents as an acute attack with a rapid increase in IOP, blurring or sudden loss of vision, appearance of haloes around lights, and pain that is often severe. When patients are predisposed to angle-closure glaucoma, their pupils should not be dilated (e.g., during an ophthalmic examination) and they should be taught the signs and symptoms of angle closure. Acute attacks can terminate without treatment, but if the IOP remains high, the optic nerve can be irreparably damaged.[1] Patients with chronic angle-closure generally experience a gradual closure of aqueous humor outflow channels, and patients can be asymptomatic until the glaucoma is in an advanced stage.[1] Permanent medical management of acute or chronic angle-closure glaucoma is difficult: Surgical procedures (e.g., peripheral iridectomies) often are needed.

PRIMARY OPEN-ANGLE GLAUCOMA

Therapeutic Agents for Treatment of Primary Open-Angle Glaucoma

INITIAL THERAPY

Historically, β-adrenergic blockers have been the most commonly prescribed first-line agents for the treatment of POAG. In recent years, prostaglandin analog (PGA) use has reached, if not exceeded, β-adrenergic blocker use. All of the ophthalmic β-blockers currently on the market are available in generic formulation, allowing for cost-effective treatment. Some of the PGAs are available as generic formulations making their cost comparable to β-blockers.

β-Adrenergic Blockers

Ophthalmic β-adrenergic antagonists block the β-adrenergic receptors in the ciliary epithelium of the eye and lower IOP primarily by decreasing aqueous humor production. On average, β-blockers decrease IOP by 20% to 35% depending on the strength used and the frequency of administration.[6–14]

Timolol (Timoptic)

Timolol, a nonselective β_1- and β_2-adrenergic antagonist, is one of the most commonly prescribed glaucoma medications. Because timolol was the first ocular β-adrenergic blocker marketed, subsequently marketed ophthalmic β-blockers usually are compared with timolol for safety and effectiveness. Concentrations or dosages exceeding one drop of timolol 0.5% twice daily (BID) do not produce further significant decreases in IOP.[15] Therapy usually is initiated with a 0.25% solution administered as one drop BID. Monocular administration of timolol has resulted in equal bilateral IOP reduction and can reduce the cost of therapy and side effects for some patients.[16] An escape phenomenon, or tachyphylaxis, can occur with timolol.

Timolol has been associated with a modest reduction of resting pulse rate (5–8 beats/minute),[17,18] worsening of heart failure, and adverse pulmonary effects (e.g., dyspnea, airway obstruction, pulmonary failure).[19,20] After chronic administration in susceptible individuals, timolol can cause corneal anesthesia.[21,22] Although uveitis has been reported in patients receiving ophthalmic timolol, a cause-and-effect relationship has not been established.[23,24]

Systemic absorption after topical administration does occur, but it may not be significant in the majority of patients. Care should be taken when timolol is used in patients with sinus bradycardia, heart failure (see Chapter 14, Heart Failure), or pulmonary disease. Systemic side effects could be exaggerated in elderly patients secondary to inadvertent overdosing associated with poor administration technique (see Case 54-1, Question 3).

Timoptic XE

Timoptic XE, a timolol ophthalmic gel-forming solution, is administered once daily. The ophthalmic vehicle, gellan gum (Gelrite), is a solution that forms a clear gel in the presence of monovalent or divalent cations.[25] This ion-activated gelation prolongs precorneal residence time and increases ocular bioavailability, allowing timolol to be administered once daily.[25] Timoptic XE is comparable to timoptic solution in lowering IOP.[26]

Levobunolol (Betagan)

Levobunolol, a nonselective β-adrenergic antagonist, is approved for either once-daily or BID administration. Levobunolol 0.5% and 1% are comparable to timolol in lowering IOP. The incidence of adverse reactions, including decreases in heart rate, is also comparable to that for timolol.[7,27]

Metipranolol (OptiPranolol)

Another nonselective β-adrenergic blocking agent, metipranolol 0.1% to 0.6%, is comparable to timolol 0.25% to 0.5% in reducing IOP.[8,9] Like timolol, metipranolol produces corneal anesthesia, which occurs within 1 minute of instillation and returns to baseline after 10 minutes.[20] Metipranolol is associated with a greater incidence of stinging or burning on administration and has been associated with granulomatous anterior uveitis.[28,29] As a result of these side effects, the use of metipranolol is limited.

Carteolol (Ocupress)

Carteolol, a nonselective β-adrenergic blocking agent with partial β-adrenergic agonist activity, theoretically should minimize the bronchospastic, bradycardic, and hypotensive effects associated with other ocular β-adrenergic blockers.[30] However, no clinical differences were seen when the cardiovascular and pulmonary function effects of carteolol were compared with those of timolol. Carteolol 1% and timolol 0.25% administered BID are equally effective in reducing IOP.[11–13]

Betaxolol (Betoptic)

In contrast to other β-adrenergic blocking ophthalmic agents, betaxolol is a selective β_1-adrenergic blocker. This cardioselective property may result in less adverse effects on pulmonary function than nonselective β-adrenergic blockers in patients with reactive airway disorders. Betaxolol is slightly less effective than timolol in IOP reduction, and more patients tend to need adjunctive therapy with betaxolol.[14,31–33]

Prostaglandin Analogs

Latanoprost (Xalatan), travoprost (Travatan Z), bimatoprost (Lumigan), and tafluprost (Zioptan) are all PGAs. Latanoprost and travoprost, and tafluprost are analogs of prostaglandin $F_{2\alpha}$, and they lower IOP by serving as selective prostaglandin $F_{2\alpha}$-receptor agonists. Bimatoprost is a synthetic prostamide analog. Tafluprost is a preservative-free formulation supplied in single-use containers.[34]

The prostaglandin analogs increase uveoscleral outflow of aqueous humor and, thereby, decrease IOP.[35] These agents often are prescribed as first-line agents for the treatment of POAG because they are at least as effective as the β-blockers, can be administered once a day, and are associated with minimal systemic adverse effects.

Latanoprost

Latanoprost (Xalatan) is approved for the initial treatment of POAG or ocular hypertension.[36] When administered once daily in the evening, latanoprost is at least as effective as timolol in decreasing IOP. When the effectiveness of latanoprost 0.005% once daily was compared with timolol 0.5% BID, the IOP-lowering effects of latanoprost were superior to those of timolol.[37,38] In addition, the nocturnal control of IOP with latanoprost was superior to that with timolol. Latanoprost 0.005% should be dosed once daily in the evening because the IOP-lowering effects of latanoprost might actually be inferior when administered more frequently.

Systemic side effects are minimal with latanoprost, but local reactions (e.g., iris pigmentation; eyelid skin darkening; eyelash lengthening, thickening, pigmentation, and misdirected growth; conjunctival hyperemia; ocular irritation; superficial punctate keratitis) are relatively common. Latanoprost can gradually increase the amount of brown pigment in the iris by increasing the melanin content in the stromal melanocytes of the iris. This pigment change occurs in 7% to 22% of patients and is most noticeable in those with green-brown, blue/gray-brown, or yellow-brown eyes.[36] The onset of increased iris pigmentation usually is noticeable within the first year of treatment and can be permanent. The nature and severity of adverse events are not affected by the increased pigmentation of the iris.

Latanoprost has additive effects when administered with β-blockers (e.g., timolol), carbonic anhydrase inhibitors (e.g., dorzolamide), and α_2-adrenergic agonists (e.g., brimonidine, apraclonidine). When added to existing therapy, latanoprost decreases IOP an additional 2.9 to 6.1 mm Hg. As a result, latanoprost is a good adjunctive ophthalmic agent for patients who are unable to adequately lower their IOP with single-agent therapy. Although the complementary IOP-lowering effects of latanoprost are comparable to those of brimonidine (at least a 15% reduction in IOP) in patients inadequately controlled on β-adrenergic blocking agents, brimonidine (an α_2-adrenergic agonist) in a comparative study was associated with fewer adverse effects on the quality of life. For example, watery or teary eyes and cold hands and feet were reported more frequently in latanoprost-treated patients.[36] The effectiveness of latanoprost when used once a day alone or as an adjunct to other IOP-lowering drugs and its relative tolerability make it one of the most common if not the most common treatment option for POAG and ocular hypertension.[37–42]

Travoprost

Travoprost (Travatan Z) is US Food and Drug Administration (FDA)-approved for the reduction of elevated IOP and ocular hypertension in patients who are intolerant or who fail to respond to other agents. Travoprost is used as a first-line agent in clinical practice because it is more effective than timolol and at least as effective as latanoprost. The mean IOP reduction with travoprost in African-American patients was 1.8 mm Hg greater than in non–African-American patients. Travoprost, as adjunctive therapy to timolol in patients not responding adequately to timolol alone, reduced IOP an additional 6 to 7 mm Hg. The side effect profile of travoprost is similar to that for latanoprost, including increased iris pigmentation and eyelash changes.[43–45] Local irritation may be less with travoprost because it is free of the preservative benzalkonium chloride (BAK). Rather, travoprost is preserved in the bottle with SofZia, which is a unique ionic buffer containing borate, sorbitol, prophylene glycol, and zinc.

Bimatoprost

Like travoprost, bimatoprost (Lumigan) once daily or BID achieved lower target IOPs than did timolol BID. Bimatoprost BID, however, was less effective than bimatoprost once a day. Iris pigmentation changed in 1.1% of bimatoprost-treated patients. In a 6-month randomized multicenter study, bimatoprost once a day lowered IOP more effectively than latanoprost once a day. Side effects were similar between treatment groups; however, conjunctiva hyperemia was more common ($p < 0.001$) in bimatoprost-treated patients. Overall, the side effect profile of bimatoprost appears to be similar to that for latanoprost and travoprost.[46–48] The local side effects seen with other PGAs also appear to be relatively common with bimatoprost. As a result, the FDA approved the cosmetic use of bimatoprost solution under the trade name Latisse. Latisse solution is applied with an applicator to the base of the

---

upper eyelashes for the treatment of hypotrichosis (inadequate eyelashes). Eyelash lengthening, thickening, and darkening or pigmentation is seen after 8 to 16 weeks of use.[49]

Tafluprost

Tafluprost (Zioptan) is a preservative-free product, US FDA-approved for the reduction of elevated IOP and ocular hypertension. Tafluprost daily in the evening is as effective as latanoprost daily in the evening and timolol 0.5% BID and has demonstrated additive efficacy when administered with timolol. Switch studies evaluating tafluprost in patients receiving BAK containing agents demonstrated some improvement in adverse effects. As a result, tafluprost is an important option for patients with a documented hypersensitivity to BAK or other PGAs. The adverse effect profile is similar to other PGAs.[50–54]

α_2-Adrenergic Agonists

Apraclonidine (Iopidine) and brimonidine (Alphagan) are selective α_2-adrenergic agonists similar to clonidine. Apraclonidine is less lipophilic than clonidine and brimonidine, does not cross the blood–brain barrier as readily, and theoretically has fewer systemic side effects (e.g., hypotension, decreased pulse, dry mouth). Brimonidine is more highly selective for α_2-adrenergic receptors than clonidine or apraclonidine and, theoretically, should be associated with fewer ocular side effects.

α_2-Adrenergic agonists appear to lower IOP by decreasing the production of aqueous humor and by increasing uveoscleral outflow.[55]

Brimonidine is an alternative first-line agent in the treatment of POAG. It may also be used as adjunctive therapy in patients not responding to other agents. Apraclonidine 1% is indicated to control or prevent postsurgical elevations in IOP after argon laser trabeculoplasty or iridotomy. The 0.5% apraclonidine solution is indicated for short-term adjunctive therapy in patients on maximally tolerated medical therapy. Long-term IOP control should be monitored closely in patients taking α_2-adrenergic agonists because tachyphylaxis can occur. Common ocular side effects include burning, stinging, blurring, conjunctival follicles, and an allergic-like reaction consisting of hyperemia, pruritus, edema of the lid and conjunctiva, and foreign body sensation. Although ocular side effects are less common with brimonidine than with apraclonidine, systemic side effects (e.g., dry nose and mouth, mild hypotension, decreased pulse, and lethargy) are more common with brimonidine. α_2-Adrenergic agonists should be used with caution in patients with cardiovascular disease, orthostatic hypotension, depression, and renal or hepatic dysfunction.[55,56] Brimonidine (Alphagan P) is available with Purite as a preservative, which facilitates drug delivery into the eye, allowing use of a lower drug concentration.[56]

The IOP-reduction effects (peak and trough) of brimonidine 0.2% BID are 14% to 28%. Although the approved dosing schedule of brimonidine is 3 times a day (TID), brimonidine 0.2% BID lowers IOP comparably to timolol 0.5% BID, and both are slightly better than betaxolol 0.25% BID.[57,58] The IOP-lowering effect of brimonidine also may be comparable to that of latanoprost; however, conflicting efficacy and tolerability results in clinical studies may be related to differences in study design.[59] The combination of brimonidine and timolol is as equally tolerable and effective as the combination of dorzolamide and timolol.[60] The FDA-approved Combigan ophthalmic solution combines an α_2-adrenergic agonist (brimonidine tartrate 0.2%) with a β-adrenergic blocker (timolol maleate 0.5%).

Topical Carbonic Anhydrase Inhibitors

Carbonic anhydrase occurs in high concentrations in the ciliary processes and retina of the eye. Carbonic anhydrase inhibitors (CAIs) lower IOP by decreasing bicarbonate production and, therefore, the flow of bicarbonate, sodium, and water into the posterior chamber of the eye, resulting in a 40% to 60% decrease in aqueous humor secretion.

Although CAIs have been used orally for many years in the treatment of elevated IOPs, they have been replaced by the topical ophthalmic CAIs, dorzolamide (Trusopt) and brinzolamide (Azopt), which are safer and better tolerated. Topical CAIs are excellent alternatives to β-blockers in the initial management of elevated IOPs, and are effective as adjunctive agents. Brinzolamide 1% TID reduces IOP comparably to that achieved with dorzolamide 2% TID and to betaxolol 0.5% BID, but slightly less than timolol 0.5% BID. The IOP-reduction effects (peak and trough) of dorzolamide 2% TID are 16% to 25%. Brinzolamide and dorzolamide are approved for TID dosing; however, BID dosing may be adequate. Dorzolamide provides additional IOP-lowering effects when added to existing β-blocker therapy.[61,62] An ophthalmic solution of dorzolamide hydrochloride and timolol maleate is marketed as Cosopt, and a combination of brinzolamide and brimonidine is marketed as Simbrinza.[63]

The combined use of topical dorzolamide and oral acetazolamide does not result in additive effects and might increase the risk of toxicity. Therefore, the concomitant use of topical and oral CAIs is not advised.[64–66]

The topical CAIs are well tolerated with few systemic side effects. The most common adverse effects reported with dorzolamide are ocular burning, stinging, discomfort and allergic reactions, bitter taste, and superficial punctate keratitis. Brinzolamide causes less burning and stinging of the eyes than dorzolamide, because its pH more closely resembles that of human tears. Dorzolamide and brinzolamide are sulfonamides and may cause the same types of adverse reactions attributable to sulfonamides. These drugs should not be used in patients with renal or hepatic impairment.[64–66]

Pilocarpine

Pilocarpine (Isopto Carpine) historically was an initial treatment of choice, but with the introduction and widespread use of newer agents, pilocarpine has fallen out of favor. Therapy usually is begun using lower concentrations (1%), one drop 4 times a day (QID). Pilocarpine is a direct-acting cholinergic (parasympathomimetic) that causes contraction of ciliary muscle fibers attached to the trabecular meshwork and scleral spur. This opens the trabecular meshwork to enhance aqueous humor outflow. There also may be a direct effect on the trabecular meshwork. Pilocarpine causes miosis by contraction of the iris sphincter muscle, but the miosis is not related to the decrease in IOP.

Carbachol

Carbachol (Isopto Carbachol) is reserved as a third-line agent in patients who are unresponsive or intolerant to initial medications. In addition to having direct cholinergic effects, carbachol is more resistant to cholinesterase than pilocarpine. Added benefits include increased release of acetylcholine from parasympathetic nerve terminals and a weak anticholinesterase effect. Carbachol is administered TID.

Anticholinesterase Agents

If control of IOP is not achieved with optimal use of other topical monotherapy and combination therapy agents, then anticholinesterase agents may be prescribed as a last topical therapy option. Anticholinesterase agents inhibit the enzyme cholinesterase, thereby increasing the amount of acetylcholine and its naturally occurring cholinergic effects.

Echothiophate Iodide

Echothiophate iodide (phospholine iodide), an irreversible cholinesterase inhibitor, primarily inactivates pseudocholinesterase and secondarily inhibits true cholinesterase. Echothiophate iodide may be used if maximal doses of other agents and combination therapy are ineffective. Echothiophate iodide has a long duration of action that affords good control of IOP; however, miosis and myopia are significant side effects. Concentrations higher than 0.06% are associated with a significant increase in subjective complaints (e.g., brow ache).[67]

COMBINATION THERAPY

In general, drugs with different pharmacologic actions have at least partially additive effects in lowering IOP in the treatment of glaucoma. Drugs with similar pharmacologic actions (i.e., from the same pharmacologic class) should not be combined because dose-related adverse effects are more likely and the incremental increase in benefits is likely to be more modest.

Timolol and other β-adrenergic blocking drugs have additive IOP-lowering effects when used in combination with miotic agents, prostaglandin analogs, α_2-agonists, and CAIs. For example, the IOP-lowering effect is greater when timolol is used in combination with pilocarpine, dorzolamide, brimonidine, and travoprost. Likewise, for example, latanoprost has additive effects when administered with timolol, dorzolamide, and α_2-adrenergic agonists.[38–42],[68–73] The trend toward the development of fixed-combination products offers many advantages in the treatment of POAG. These advantages include improved adherence because of a reduction in the number of dosages and bottles, eliminating the need to instill two separate drugs 5 to 10 minutes apart to prevent a washout effect from the second medication, improving safety and tolerability by limiting the exposure to the BAK preservative, and a cost savings for the patient by potentially eliminating a copay for one of the medications. There are two β-adrenergic blocker combination products currently on the market, timolol/dorzolamide (Cosopt) and brimonidine/timolol (Combigan). The IOP-lowering effects of timolol/dorzolamide (Cosopt) are comparable to or greater than those of latanoprost monotherapy.[65] Brinzolamide and brimonidine are combined and available as Simbrinza.[63]

Predisposing Factors

CASE 54-1

QUESTION 1: M.H., a 52-year-old African-American woman with brown eyes, presented for routine ophthalmic examination. Visual acuity without correction was 20/40 right eye and 20/80 left eye. Tonometry measured an IOP of 36 mm Hg in both eyes. Ophthalmoscopy revealed physiologic cupping of the optic discs in both eyes, and visual field examination revealed a nerve fiber bundle defect consistent with glaucoma. Pupils were normal in both eyes, and gonioscopy indicated that anterior chamber angles were open in both eyes. There were no signs of cataract formation. M.H. related a positive family history for glaucoma and presently is being treated for hypertension, chronic heart failure (CHF), chronic obstructive pulmonary disease, and asthma. Her medications include the following:

Amitriptyline, 75 mg at bedtime
Chlorpheniramine, 4 mg every 6 hours as needed (PRN)
Lisinopril, 10 mg once daily
Furosemide, 40 mg BID
Nitroglycerin, 0.3 mg sublingual PRN
Fluticasone/salmeterol 250/50 mcg dry powder inhaler, one inhalation twice daily
Albuterol 90 mcg metered-dose inhaler, 1 to 2 puffs QID PRN
Tiotropium bromide inhaler, 18 mcg inhaled once daily

Findings on examination indicate that M.H. has POAG. What other factors may predispose M.H. to an increased IOP?

POAG is thought to be determined genetically, and M.H. has a positive family history. The disease is more prevalent and aggressive in African-Americans.[1] In addition, she is taking several medications that have been associated with increases in IOP.

ANTICHOLINERGIC DRUGS

Most reports dealing with drug-induced increases in IOP center around precipitation of angle-closure glaucoma by ophthalmic mydriatic or cycloplegic agents (anticholinergics). In patients with open-angle glaucoma, topical anticholinergics can significantly increase resistance to aqueous humor outflow and elevate IOP while the anterior chamber remains grossly open.[4] As part of any routine ophthalmic examination, the pupils are dilated with a mydriatic or cycloplegic agent (unless otherwise contraindicated). The IOP is always measured before this procedure, so the use of these agents would not have influenced the IOP readings in M.H.

If systemic anticholinergic agents are administered in doses sufficient to cause pupillary dilation, the risk of precipitating angle-closure increases. However, it is unlikely that these agents will aggravate open-angle glaucoma unless the amount reaching the eye is sufficient to cause cycloplegia.[4] Although literature documentation of POAG exacerbation by these agents is scarce, medications with anticholinergic side effects (e.g., antihistamines, benzodiazepines, disopyramide, phenothiazines, tricyclic antidepressants, tiotropium) should be considered. M.H. is receiving chlorpheniramine as needed, amitriptyline at bedtime, and tiotropium bromide once daily, but her pupil examination is normal with no evidence of mydriasis or cycloplegia. Therefore, it is highly unlikely that these medications contributed to her increased IOP.

ADRENERGIC DRUGS

Adrenergic agents, such as central nervous system stimulants, vasoconstrictors, appetite suppressants, and bronchodilators, may produce minimal pupillary dilation. These have no proven adverse influences on IOP in patients with either normal eyes or eyes with open-angle glaucoma. Consequently, the use of salmeterol and albuterol in M.H. is also an unlikely source of the increased IOP.

OTHER DRUGS

Conclusive evidence for the production of angle-closure glaucoma by vasodilators is lacking, although slight increases in IOP have been reported. Use of nitroglycerin as needed in M.H. is not a cause for concern. There have been isolated reports of other medications causing mydriasis in glaucoma patients. These include muscle relaxants (carisoprodol), monoamine oxidase inhibitors, fenfluramine, ganglionic blocking agents, salicylates, and oral contraceptives. Succinylcholine, ketamine, and caffeine have been associated with increases in IOP. Corticosteroid-induced IOP elevation will be addressed in Case 54-8, Question 2. If M.H. requires administration of any other medications associated with increases in IOP, the risk of potential adverse effects can be minimized by routine follow-up.

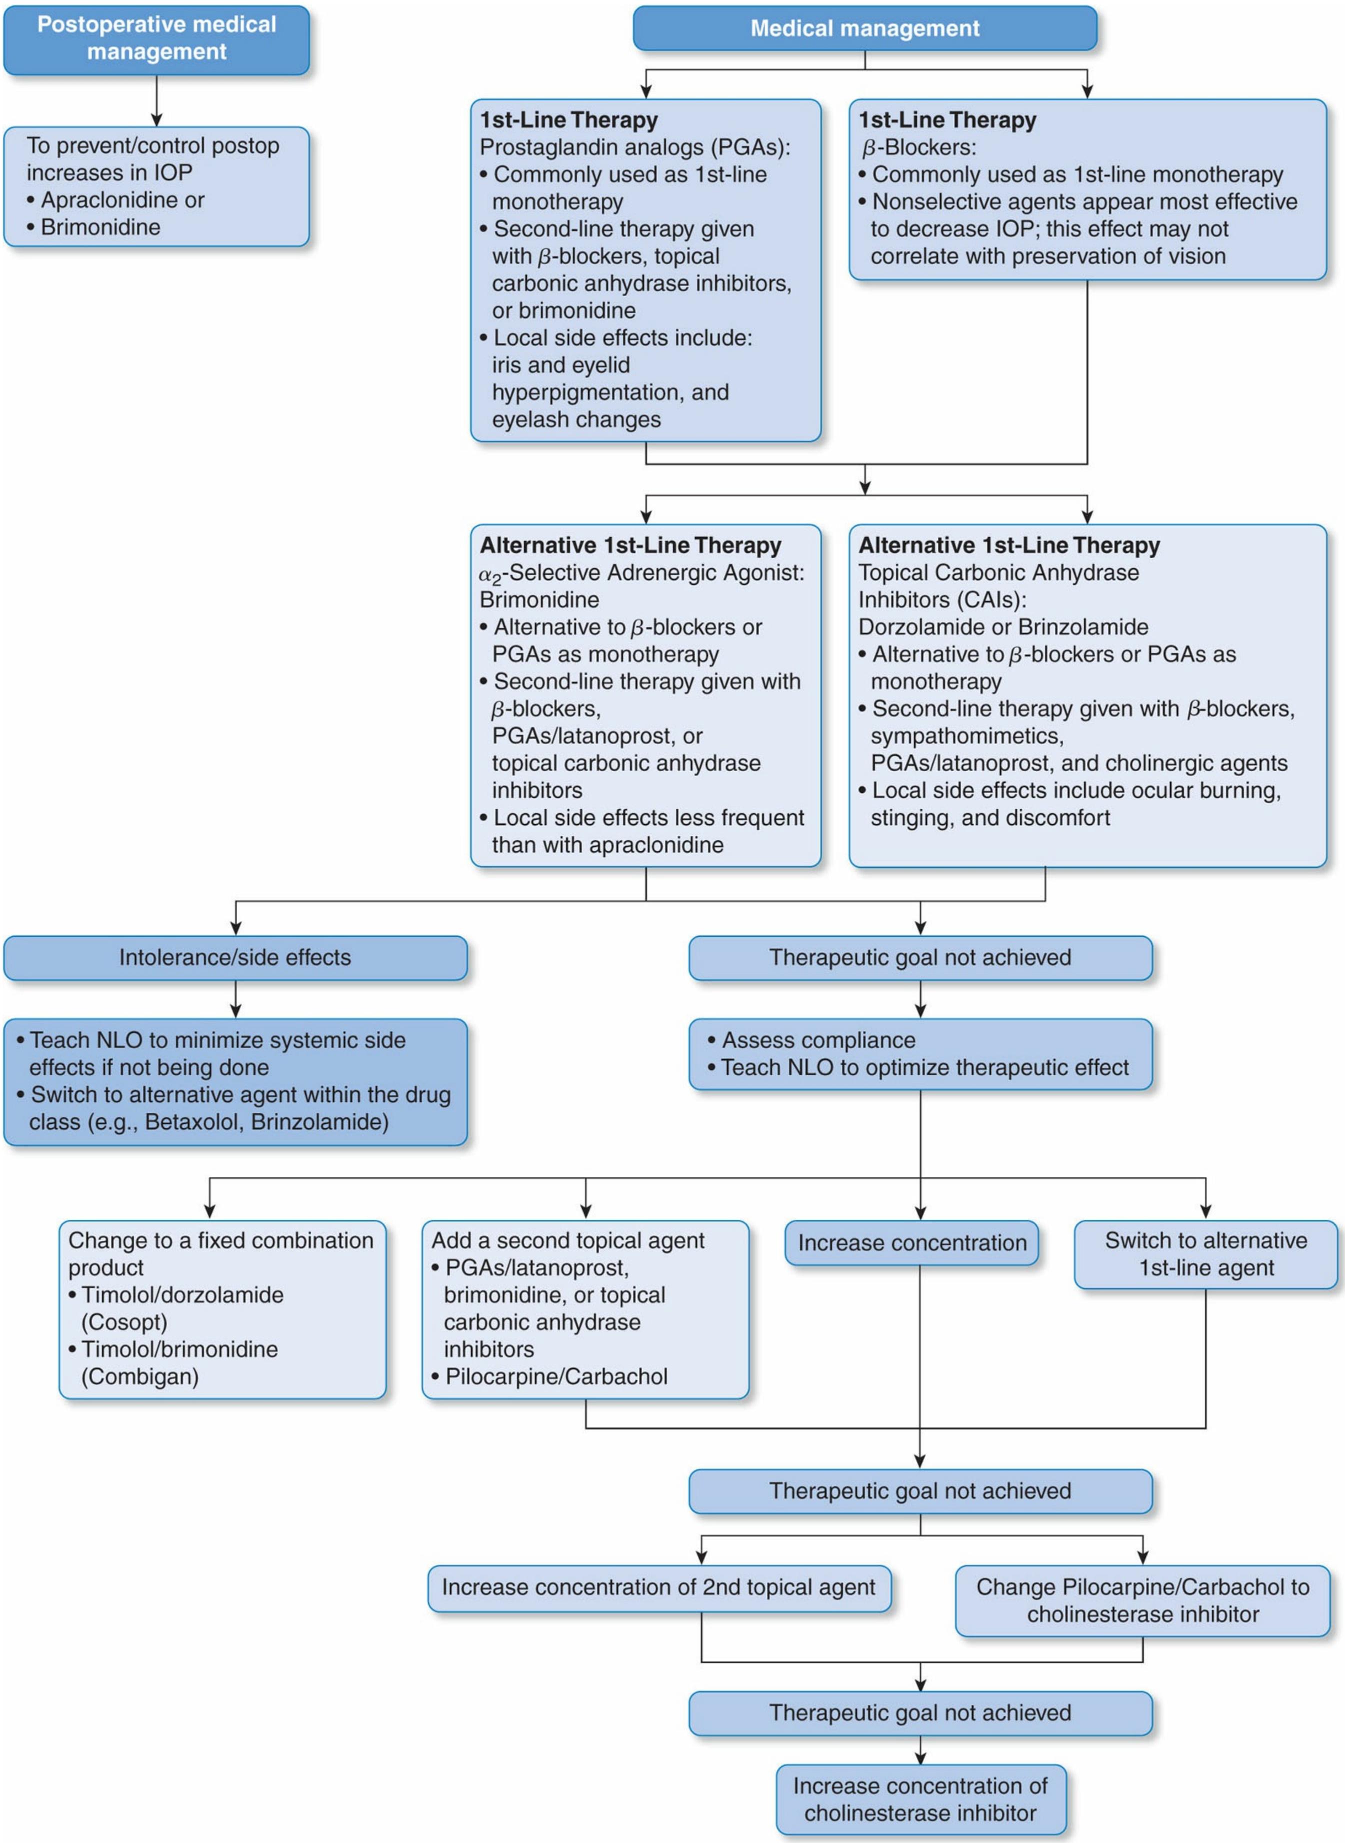
Initial Therapy

CASE 54-1, QUESTION 2: What is the best initial therapeutic treatment in M.H.?

Topical β-blockers or PGAs are the initial agents of choice in the treatment of POAG (Fig. 54-2). Their efficacy is well documented in numerous studies, and side effects are well characterized. Brimonidine (Alphagan) and topical CAIs are alternative first-line agents. Table 54-1 lists the common topical agents used in the treatment of POAG.

Timolol or other nonselective β-adrenergic blockers should not be initiated for M.H. because of her history of asthma (the indications and use of β-blockers for patients with heart failure are described in Chapter 14, Heart Failure). Betaxolol, a β_1-adrenergic blocker, is better tolerated than the nonselective β-adrenergic blocker, timolol, in patients with reactive airway disease and should be considered when topical β-blocker therapy is indicated in patients such as M.H.[12,31,32,74] Betaxolol 0.25% suspension BID would be reasonable for the initial treatment of M.H.'s glaucoma. Nevertheless, adverse pulmonary and cardiac side effects can occur with betaxolol: M.H. should be followed up closely for these adverse effects. Although ocular burning and stinging have been associated more frequently with betaxolol and metipranolol than with other topical β-blockers, the 0.25% suspension is better tolerated than the 0.5% solution and is as effective.[31] Brimonidine, a topical CAI, and a PGA (e.g., latanoprost) are acceptable alternatives to betaxolol as initial therapy.

Although brimonidine, topical CAIs, and latanoprost may not exacerbate her asthma or CHF, they can cause localized side effects and brimonidine can cause systemic hypotension and lethargy.



Postoperative medical management
To prevent/control postop increases in IOP • Apraclonidine or • Brimonidine
Medical management
1st-Line Therapy Prostaglandin analogs (PGAs): • Commonly used as 1st-line monotherapy • Second-line therapy given with β-blockers, topical carbonic anhydrase inhibitors, or brimonidine • Local side effects include: iris and eyelid hyperpigmentation, and eyelash changes
1st-Line Therapy β-Blockers: • Commonly used as 1st-line monotherapy • Nonselective agents appear most effective to decrease IOP; this effect may not correlate with preservation of vision
Alternative 1st-Line Therapy α2-Selective Adrenergic Agonist: Brimonidine • Alternative to β-blockers or PGAs as monotherapy • Second-line therapy given with β-blockers, PGAs/latanoprost, or topical carbonic anhydrase inhibitors • Local side effects less frequent than with apraclonidine
Alternative 1st-Line Therapy Topical Carbonic Anhydrase Inhibitors (CAIs): Dorzolamide or Brinzolamide • Alternative to β-blockers or PGAs as monotherapy • Second-line therapy given with β-blockers, sympathomimetics, PGAs/latanoprost, and cholinergic agents • Local side effects include ocular burning, stinging, and discomfort
Intolerance/side effects
• Teach NLO to minimize systemic side effects if not being done • Switch to alternative agent within the drug class (e.g., Betaxolol, Brinzolamide)
Therapeutic goal not achieved
• Assess compliance • Teach NLO to optimize therapeutic effect
Change to a fixed combination product • Timolol/dorzolamide (Cosopt) • Timolol/brimonidine (Combigan)
Add a second topical agent • PGAs/latanoprost, brimonidine, or topical carbonic anhydrase inhibitors • Pilocarpine/Carbachol
Increase concentration
Switch to alternative 1st-line agent
Therapeutic goal not achieved
Increase concentration of 2nd topical agent
Change Pilocarpine/Carbachol to cholinesterase inhibitor
Therapeutic goal not achieved
Increase concentration of cholinesterase inhibitor

Figure 54-2 Medical management of glaucoma. IOP, intraocular pressure; NLO, nasolacrimal occlusion.

Table 54-1

Common Topical Agents Used in the Treatment of Open-Angle Glaucoma

Generic	Mechanism	Strength	Usual Dosage	Comments
β-Blockers				
Betaxolol (Betoptic [solution], Betoptic S [suspension])	Sympatholytic	0.25% (suspension) 0.5% (solution)	1 drop BID 1 drop BID	Shake suspension well before use. Effective with few associated ocular side effects. BID dosage enhances compliance. Considered β-blocker of choice in patients with preexisting HF or pulmonary disease because of β_1-adrenergic specificity. Patient response may be less than that seen with timolol
Carteolol (Ocupress)	Sympatholytic	1%	1 drop BID	Effective with few associated side effects. BID dosage enhances compliance. Use with caution in patients with preexisting HF or pulmonary disease
Levobunolol (Betagan)	Sympatholytic	0.25%, 0.5%	1 drop daily or BID	Effective with few associated ocular side effects. Daily and BID dosage enhances compliance. Use with caution in patients with preexisting HF or pulmonary disease
Metipranolol (OptiPranolol)	Sympatholytic	0.3%	1 drop BID	Effective with few associated side effects. BID dosage enhances compliance. Use with caution in patients with preexisting HF or pulmonary disease
Timolol (Timoptic) (Betimol) (Istalol)	Sympatholytic	0.25%, 0.5% 0.5% (Istalol) 0.25%, 0.5% preservative-free (Timoptic Ocudose)	1 drop BID 1 drop daily in morning (Istalol)	Effective with few associated ocular side effects. Daily and BID dosage enhances compliance. Use with caution in patients with preexisting HF or pulmonary disease. Proven long-term effectiveness, with well-defined side effect profile
Timolol Gel-Forming Solution (Timoptic XE, Timolol GFS)	Sympatholytic	0.25%, 0.5%	1 drop daily	Once-daily timolol formulation. The ophthalmic vehicle, gellan gum (Gelrite), prolongs precorneal residence time and ↑ ocular

				bioavailability, allowing once-daily administration
α2-Selective Adrenergic Agonists				
Apraclonidine (Iopidine)	Sympathomimetic	0.5%, 1%	1 drop preoperatively and postoperatively or 1 drop BID to TID	May be used preoperatively and postoperatively for the prevention of ↑ IOP after anterior-segment laser procedures. Use of NLO minimizes systemic side effects and allows for BID dosing. Does not penetrate the blood–brain barrier, therefore negligible systemic hypotension. Local adverse effects fairly common. Tachyphylaxis may be observed
Brimonidine (Alphagan)	Sympathomimetic	0.15%, 0.2%	1 drop BID to TID	Effective long-term monotherapy or adjunctive therapy. Use of NLO minimizes systemic side effects and allows for BID dosing. Penetrates the blood–brain barrier, therefore may cause mild systemic hypotension and lethargy. Local adverse effects less common than with apraclonidine
Brimonidine (Alphagan P)	Sympathomimetic	0.1%, 0.15%	1 drop BID to TID	Contains Purite preservative. Purite preservative and lower concentrations may improve tolerability

---

Topical Carbonic Anhydrase Inhibitors				
Brinzolamide (Azopt)	Decreased aqueous humor production	1%	1 drop TID	Shake suspension well before use. Effective long-term monotherapy or adjunctive therapy. Well tolerated with few systemic side effects. Less burning and stinging compared with dorzolamide
Dorzolamide (Trusopt)	Decreased aqueous humor production	2%	1 drop TID	Effective long-term monotherapy or adjunctive therapy. Well tolerated with few systemic side effects

Prostaglandin Analogs				
Latanoprost (Xalatan)	Prostaglandin $F_2\alpha$ agonist	0.005%	1 drop once a day at bedtime	BID dosing may be less effective than once a day at bedtime dosing. May cause increased pigmentation of the iris and eyelid. Systemic side effects are rare, but may cause muscle, joint, back pain, headaches, migraines, and skin rash. Effective monotherapy or adjunctive therapy. Store unopened bottles in refrigerator. Opened bottles may be stored at room temperature up to 6 weeks
Travoprost (Travatan Z)	Prostaglandin $F_2\alpha$ agonist	0.004%	1 drop once a day at bedtime	BID dosing may be less effective than once a day at bedtime dosing. May cause increased pigmentation of the iris and eyelid. Systemic side effects are rare, but may include colds and upper respiratory tract infections. Effective monotherapy or adjunctive therapy with timolol. May be more effective than timolol and latanoprost and more effective in African-Americans. Does not contain benzalkonium chloride as a preservative. Contains the preservative SofZia that may be better tolerated
Bimatoprost (Lumigan)	Prostamide	0.01%, 0.03%	1 drop once a day at bedtime	BID dosing may be less effective than QHS dosing. May cause increased pigmentation of the iris and eyelid. Systemic side effects are rare but include colds and upper respiratory tract infections and headache. May be more effective than timolol and latanoprost
Tafluprost (Zioptan)	Prostaglandin $F_2\alpha$ agonist	0.0015% preservative-free dropperette	1 drop once a day at bedtime	BID dosing may be less effective than QHS dosing. May cause increased pigmentation of the iris and eyelid. Systemic side effects are rare but include common cold, cough, headache, and urinary tract infections.

				Store unopened foiled pouches in refrigerator. Single-use container may be stored in the opened foil pouch for 28 days at room temperature
Miotics				
Pilocarpine (Isopto Carpine)	Parasympathomimetic	1%, 2%, 4%	1–2 drops TID or QID	Long-term proven effectiveness. Little rationale for administration more frequently than every 4 hours. Side effects of miosis with decreased vision and brow ache are common sources of patient complaints.
Carbachol (Isopto Carbachol)	Parasympathomimetic	1.5%, 3%	1–2 drops TID or QID	Used in patients allergic to or intolerant of other miotics. May be used as frequently as every 4 hours. Corneal penetration is enhanced by benzalkonium chloride in commercial preparations. Side effects are similar to those of pilocarpine

---

Echothiophate iodide (phospholine iodide)	Anticholinesterase	0.125%	1 drop BID	Long duration, although usually dosed BID, which enhances compliance. Available as powder + diluent; after reconstitution, stable 30 days at room temperature, 6 months refrigerated. Side effects similar to those of pilocarpine. Increased cataract formation has been associated with its use
Combination Products				
Brimonidine tartrate 0.2%/timolol 0.5% (Combigan)	Sympathomimetic/sympatholytic	0.2%/0.5%	1 drop BID	Combination products may improve adherence. Eliminates the 5- to 10-minute wait between instillation of drops
Dorzolamide 2%/timolol 0.5%	Decreased aqueous humor production/sympatholytic	2%/0.5% 2%/0.5%	1 drop BID	Combination products may improve adherence.

(Cosopt)		preservative free (Cosopt PF)		Eliminates the 5- to 10-minute wait between instillation of drops
Brinzolamide 1%/brimonidine 0.2% (Simbrinza)	Decreased aqueous humor production/sympathomimetic	1%/0.2%	1 drop TID	Shake suspension well before use. Combination products may improve adherence. Eliminates the 5- to 10-minute wait between instillation of drops

BID, twice daily; HF, heart failure; IOP, intraocular pressure; NLO, nasolacrimal occlusion; QHS, every day at bedtime; GFS, gel-forming solution; QID, 4 times a day; TID, 3 times a day.

Patient Education

CASE 54-1, QUESTION 3: Betaxolol 0.25% suspension, one drop in both eyes BID, is ordered for M.H. How should M.H. be instructed regarding the proper use of her betaxolol and expected therapeutic side effects?

M.H. should be instructed to hold the inverted betaxolol bottle between her thumb and middle finger and to rest that hand on her forehead to minimize the risk of inadvertent eye injury caused by sudden unexpected movement of the hand. The index finger is left free to depress the bottom of the container, releasing one drop for the dose. With a little practice, this technique is easy to master. The lower eyelid should be drawn downward with the index finger of the opposite hand or pinched between the thumb and index finger to form a pouch. The patient should look up and administer the drug into the pouch of the eye.

Patients must be encouraged to continue regular use of their medications for effective treatment of glaucoma. Chronic glaucoma is a silent disease and often not associated with symptoms; therefore, the continuation of therapy should be encouraged continuously in patients, especially when side effects to drug therapy can be encountered. Betaxolol is best administered every 12 hours because this schedule of administration is consistent with its duration of action (see Table 54-1).

Systemic side effects (e.g., bradycardia, heart block, CHF, pulmonary distress, central nervous system) are rare with betaxolol, but M.H. should be instructed to report any of these effects to her primary-care provider.

NASOLACRIMAL OCCLUSION

CASE 54-1, QUESTION 4: How much would occlusion of the nasolacrimal ducts (punctal occlusion) by M.H. influence systemic absorption or alter the therapeutic effects of betaxolol?

Nasolacrimal, or punctal, occlusion is a technique that can decrease the amount of drug absorbed systemically.[75] Occlusion of the puncta (through the application of slight pressure with the finger to the inner corner of the eye closest to the nose for 3 to 5 minutes during and after drug instillation) can minimize systemic absorption of ophthalmic medications (e.g., betaxolol), decrease the incidence of side effects, and improve medication effectiveness.[75–77] When a single drop of ophthalmic timolol 0.5% was instilled into the eyes of patients at various times before cataract surgery and the nasolacrimal duct was occluded for 5 minutes, drug levels in the aqueous humor were significantly greater in patients who had their nasolacrimal ducts occluded than those who did not.[76]

Nasolacrimal occlusion is effective and can maximize drug benefits because a lower concentration of an ophthalmic formulation can be used and the dose can be administered less frequently.[69]

Alternative Therapy

CASE 54-1, QUESTION 5: Two weeks after initiation of therapy, M.H. returns to clinic for a follow-up evaluation. Her IOP measures 32 mm Hg in the right eye and 30 mm Hg in the left eye. She denies nonadherence and has no complaints of intolerable side effects. How should therapy be altered? Are there alternative dosage forms or drugs that can be used?

Betaxolol may not be as effective as other ocular β-blockers. Therefore, adjunctive therapy may be required. However, M.H. should be evaluated to determine whether she has been using the technique of nasolacrimal occlusion. If not, M.H. should be again instructed on the technique of nasolacrimal occlusion and the importance of this technique in achieving the maximal therapeutic effect of her therapy (see Case 54-1, Question 4).

After the initiation of therapy, patients should be seen for a follow-up evaluation within about 2 weeks. If M.H. has been adherent to therapy and has been occluding her nasolacrimal ducts, a new course of action is needed because her IOP still is elevated. When the goal of therapy has not been achieved, the drug concentration of the ophthalmic formulation can be increased, adjunctive therapy (e.g., brimonidine, a topical CAI, a PGA) can be initiated, or an alternative first-line agent can be selected. Patients who are experiencing unstable reductions of IOP should be followed up within 4 months.[5] Stable patients usually are evaluated every 6 to 12 months.[5]

Adverse Effects

CASE 54-1, QUESTION 6: Several weeks later, dorzolamide 2% solution, one drop both eyes BID, is added to M.H.'s betaxolol therapy. Two weeks later, M.H. returns for a follow-up evaluation and complains of bilateral stinging and foreign body sensation. Her IOP measures 30 mm Hg in the right eye and 29 mm Hg in the left eye. What are the possible causes of her side effects and poor response to therapy?

The exposure of dorzolamide to the outside environment may result in the aggregation of dry white granules on the tip of the dorzolamide bottle. These granules can drop into a patient's eyes when instilling the medication, leading to local side effects, such as stinging and foreign body sensation. Such foreign bodies may cause enough discomfort to induce nonadherence, resulting in a poor response to therapy. These granules may be rinsed off of the tip with sterile water. M.H. should be questioned about the presence of dry white granules on the tip of her dorzolamide bottle.[78]

These complaints may also be a side effect from the medications, regardless of the granule presence. Ocular burning, stinging, and discomfort were reported in one-third of patients in dorzolamide clinical trials. M.H.'s administration technique should also be assessed to determine whether she is administering the two drugs at least 5 to 10 minutes apart so that the first drug is not washed away by the second drug. This should be a consideration when assessing her response to therapy.[15]

CASE 54-1, QUESTION 7: After further discussions with M.H., it is determined that she has not been adherent to her dorzolamide therapy because of intolerable side effects. The dorzolamide is discontinued and replaced with travoprost 0.004% one drop both eyes once a day at bedtime. Why might this drug selection be especially appropriate for M.H.? What patient education information should be provided to M.H. about travoprost side effects?

Prostaglandin analogs are first-line agents and are appropriate in patients who are not responding to or are having intolerable side effects from other medications. Travoprost is an ideal choice for M.H., because African-Americans respond especially well to travoprost.[43] M.H. still needs to be informed about the PGA-induced potential for hyperpigmentation of the iris, which may be permanent. She also needs to be educated on the possibility of eyelid skin darkening and increased thickness, length, and pigmentation of her eyelashes, which all may or may not be reversible. These side effects might not be as cosmetically concerning to M.H., because she has brown eyes and will be instilling travoprost eyedrops into both eyes.

ANGLE-CLOSURE GLAUCOMA

Treatment

CASE 54-2

QUESTION 1: D.H., a 72-year-old man, presents to the emergency department with an intensely red right eye, a "steamy" appearing cornea, complaints of haloes around lights, and extreme pain. A diagnosis of acute angle-closure glaucoma is made. How should D.H. be managed?

D.H. should be seen by an ophthalmologist because acute angle-closure glaucoma is a medical emergency. Medical treatment usually consists of pilocarpine 2% to 4%, one drop every 5 minutes for 4 to 6 administrations. It is recommended that the puncta be covered during administration to decrease the possibility of systemic absorption. Stronger miotic agents are contraindicated because they may potentiate angle closure. Topical timolol also has been used in acute angle-closure glaucoma, commonly in combination with pilocarpine. However, drugs that decrease aqueous humor production may be ineffective in this situation because they have a decreased ability to reduce aqueous production if the ciliary body is ischemic.[5]

HYPEROSMOTIC AGENTS

Hyperosmotic agents (Table 54-2) act by creating an osmotic gradient between the plasma and ocular fluids.[79] Agents that are confined to the extracellular fluid space (e.g., mannitol) provide a greater effect on blood osmolality at the same dosage than do agents distributed in total body water.[79] Intravenously administered drugs provide a faster, somewhat greater effect than oral agents. Palatability may be a problem with oral agents and can be improved by serving these agents over crushed ice or with lemon juice or cola flavoring.

Orally, 50% glycerin is the usual drug of choice and is administered in dosages of 1 to 1.5 g/kg.[80] Isosorbide is an alternative, especially in diabetic patients because it is not metabolized to provide calories.[81] Parenterally, mannitol is the drug of choice. It is administered in doses of 1 to 2 g/kg, is not metabolized to provide calories, and may be used in patients with renal failure.[82,83]

Primary side effects of hyperosmotic agents include headache, nausea, vomiting, diuresis, and dehydration. It is important that the patient not be allowed to drink because this will counteract the osmotic effects of these agents.

Precipitation of pulmonary edema and CHF has been reported with hyperosmotic agents, and an allergic reaction has been reported with mannitol.[84]

Acetazolamide (Diamox) 500 mg intravenously may be administered in addition to hyperosmotic agents.

Table 54-2

Hyperosmotic Agents

Generic	Mode of Administration	Strength	Onset	Peak	Duration	Dose	Ocular Penetration	Distribution
Mannitol	IV	5%, 10%, 15%, 20%	30–60 minutes	1 hour	6–8 hours	1–2 g/kg	Very poor	E
Glycerin	PO	50%	10–30 minutes	30 minutes	4–5 hours	1–1.5 g/kg	Poor	E
Isosorbide	PO	45%	10–30 minutes	1 hour	5 hours	1.5–2 g/kg	Good	TBW

E, extracellular water; IV, intravenous; PO, orally; TBW, total body water.

OCULAR SIDE EFFECTS OF DRUGS

CASE 54-3

QUESTION 1: B.C., a 64-year-old man, has a history of hypertension managed with hydrochlorothiazide 25 mg/day. He takes amiodarone 800 mg/day for cardiac arrhythmia, and chlorpheniramine 12 mg BID PRN for allergies. Four weeks ago, risperidone 1 mg BID was added to his medication regimen. He also takes sildenafil 100 mg an average of twice weekly. He complains of occasional blurred vision. Could these symptoms be related to his medications?

All the drugs that B.C. is taking have been associated with ocular side effects. Thiazide diuretics have been associated with acute myopia that may last from 24 to 48 hours.[85,86] However, hydrochlorothiazide is an unlikely cause of B.C.'s blurred vision considering its recent onset.

Amiodarone can cause keratopathy, but it is asymptomatic.[87,88] A high percentage of patients who receive this drug exhibit microdeposits within the corneal epithelium that resembles the verticillate keratopathy induced by chloroquine.[85] These corneal deposits are bilateral, dose- and duration-related, reversible, and unassociated with visual symptoms.

Risperidone has been associated with disturbances of accommodation and blurred vision.[89]

B.C. may be in the approximately 1% of the population who experiences blurred vision with chlorpheniramine. This effect has been seen in patients receiving 12 to 14 mg/day.[85] If an antihistamine is indicated, an agent such as cetirizine would be less likely to cause such an effect. Sildenafil has been associated with change in color and light perception as well as blurred vision.[90] These effects generally subside within 4 hours of the dose.

Table 54-3[85–114] outlines some of the more common ocular side effects associated with systemic medications. Each case should be evaluated individually and alternative therapy considered in intolerant patients.

Table 54-3

Ocular Side Effects of Systemic Medications

Drug Class	Effect(s)	Clinical Remarks
Analgesics		

Ibuprofen	Reduced vision	Rare; blurred vision reported in patients taking from four 200-mg tablets/week to six tablets/day; changes in color vision rarely reported[91]
Narcotics, including pentazocine	Miosis	Miosis often with morphine in normal doses: slight with other agents; effect secondary to CNS action on the pupillo-constrictor center[85]
	Tearing Irregular pupils Paresis of accommodation Diplopia	Effects associated with narcotic withdrawal[85]
Antiarrhythmics		
Amiodarone	Keratopathy	Dose and duration related; resembles chloroquine keratopathy. Corneal deposits are bilateral, reversible, and unassociated with visual symptoms. Patients taking 100–200 mg/day have only minimal deposits. Deposits occur in almost 100% of patients receiving 400 mg/day[87,88]
	Cataracts	Previously reported as insignificant, anterior subcapsular lens opacities have been associated with amiodarone therapy. Rarely, such opacities may progress, increasing in density and in the diffuse distribution of the deposits, ultimately covering an area somewhat larger than the undilated pupil's aperture. The mechanism for this effect is unclear, but like chlorpromazine, amiodarone is a photosensitizing agent. Given that the lens changes are limited largely to the pupillary aperture, light exposure may result in the lens changes[85–88]
	Optic neuropathy	Approximately 2% of patients experience optic neuropathy[90]
Anticholinergics		
Atropine Dicyclomine Glycopyrrolate Propantheline Scopolamine Trihexyphenidyl	Mydriasis Cycloplegia with ↓ accommodation Photophobia	Systemic and transdermal anticholinergic agents may cause mydriasis and, less frequently, cycloplegia. Mydriasis may precipitate angle-closure glaucoma. Photophobia is related to the mydriasis. Accommodation for near objects[85,92]
Anticonvulsants		
Carbamazepine	Diplopia Blurred vision	Ocular adverse reactions when dosage >1–2 g/day; disappear when dosage is reduced[85]
Phenytoin	Nystagmus cataracts	Nystagmus in patients with high blood levels (>20 mcg/mL); rarely occurs with other hydantoins. Cataracts may occur rarely with prolonged therapy[85,93]
Topiramate	Acute myopia, secondary angle-closure glaucoma	Topiramate has been associated with angle-closure glaucoma. Symptoms including ocular pain, headache, nausea, vomiting, hyperemia, visual field defects, and blindness have been reported. This process is usually bilateral, but if symptoms are recognized and the drug is stopped in a timely manner, adverse outcomes may be minimized[90]
Trimethadione	Visual glares	A prolonged glare or dazzle occurs when eyes are exposed to light. The glare is reversible, occurs at the retinal level, and is more

		common in adolescents and adults; rarely in young children[85]
Vigabatrin	Visual field abnormalities	Visual field abnormalities including bilateral, symmetrical, and irreversible peripheral constriction occur in up to 30% of patients. Most patients are asymptomatic, and <0.1% of patients are clinically affected[90]
Anesthetics		
Propofol	Inability to open eyes	6 of 50 patients undergoing ENT procedures using standardized anesthesia with propofol were unable to open their eyes either spontaneously or in response to verbal commands. This effect lasted from 3 to 20 minutes after the end of anesthetic administration. Two patients showed complete loss of ocular motility. This was a transient, myasthenia-like weakness[94]
Antidepressants		
Tricyclic antidepressants (TCAs)		Mydriasis is the most common ocular side effect of TCAs. Cycloplegia is rare. Reports of precipitation of angle-closure glaucoma.[85]
Fluoxetine	Mydriasis Eye tics	Administration of fluoxetine 20–40 mg/day has been associated with paroxysmal contractions of the muscles around the lateral aspect of the eye. This effect occurred 3–4 weeks after initiation of fluoxetine therapy and resolved within 2 weeks of discontinuation[95]
Antihistamines		
Chlorpheniramine	Blurred vision Mydriasis, decreased lacrimal secretions	Blurred vision occurs rarely (about 1% of patients taking 12–14 mg/day)[85] Rare[85]
Antihypertensives		
Clonidine	Miosis	Miosis is seen in overdose[85]
	Dry itchy eyes	Rare[85]
Diazoxide	Lacrimation	About 20% experience lacrimation, which may continue after drug is discontinued[85]
Guanethidine	Miosis Ptosis Conjunctivitis Blurred vision	Sporadically documented. One study reported a 17% incidence of blurred vision in patients taking guanethidine 70 mg/day[85]
Reserpine	Miosis	Miosis is slight, but can last up to 1 week after a single dose[85]
	Conjunctivitis	Common, secondary to dilation of conjunctival blood vessels[85]

Anti-Infectives		
Amantadine	Corneal lesions	Diffuse, white punctate subepithelial corneal opacities have been

		reported, occasionally associated with superficial punctate keratitis. Onset has been 1–2 weeks after initiation of therapy with dosages of 200–400 mg/day. Resolves with drug discontinuation[96]
Chloramphenicol	Optic neuritis	Rare unless a total dose of 100 g and duration >6 weeks are exceeded. Vision usually improves after the drug is discontinued[85]
Chloroquine	Corneal deposits	Some patients using ordinary doses may develop corneal deposits in a few months. The deposits are visible with use of a biomicroscope and appear as white-yellow in color, but are of no consequence[85]
	Retinopathy (macular degeneration)	Serious retinopathy when total dose >100 g. Usually develops after 1–3 years; can occur in 6 months. Visual loss may be peripheral, with progression to central vision loss and disturbance of color vision. Rarely, effects such as blurred vision are seen earlier when larger doses (500–700 mg/day) are used. Macular changes may progress after drug is discontinued. These agents concentrate in pigmented tissue[85]
Ethambutol	Retrobulbar neuritis	At dosages of 15 mg/kg/day, virtually void of ocular side effects. Such effects are rare at dosages of 25 mg/kg/day for a duration of a few months. Patients treated for prolonged periods should have routine visual examinations including visual fields. Most effects are reversible after the drug is discontinued, but optic neuritis may continue to progress for 1–2 months after the drug has been discontinued[85,90]
Gentamicin	Pseudotumor cerebri	Rare, but has been well documented with secondary papilledema and visual loss[85]
Isoniazid	Optic neuritis	Prevalence not well defined, but appears to be significantly less than peripheral neuritis. Evaluation difficult because most patients are malnourished, chronic alcoholics, or receiving multiple medications. Preexisting eye disease does not appear to be a predisposing factor[85]
Nalidixic acid	Visual sensations	Most common ocular side effect. Main feature is a brightly colored appearance of objects; occurs soon after the drug is taken. Although quinolone antibiotics are nalidixic acid derivatives, they have rarely been associated with these ocular side effects[85]
	Visual loss	Temporary effect (30 minutes–3 days)
	Papilledema	Primarily in infants and young children and secondary to intracranial pressure; reversible on withdrawal of the drug
Sulfonamides	Myopia	Acute and reversible; most common ocular side effect[85]
	Conjunctivitis	Primarily with topical sulfathiazole, 4% incidence between 5 and 9 days of therapy[85]
	Optic neuritis	Even in low dosages. Usually reversible with complete recovery of vision[85]
	Photosensitivity	Associated with use of sulfisoxazole lid margin therapy[97,98]
Tetracyclines	Myopia	Appears to be acute, transient, and rare[85]
	Papilledema	More common in children and infants than adults; rare[85]
Voriconazole	Altered visual perception	May be associated with higher doses or plasma concentrations[99]

	Blurred vision	
Anti-Inflammatory Agents (also see Analgesics; Corticosteroids)		
Cyclooxygenase-2 inhibitors	Blurred vision Conjunctivitis	Discontinuation of therapy leads to resolution without long-term effects[90]
Gold	Corneal Conjunctival deposits	Deposition in the conjunctiva and superficial cornea more common than in the lens or deep cornea. Incidence in cornea of 40%–80% in total doses of 1.5 g; visual acuity is unaffected. One reported case after oral therapy[85]
Indomethacin	Decreased vision	Rare; also changes in color vision have been rarely reported.[85]
Phenylbutazone	Decreased vision	Most common ocular side effect with this drug may be caused by lens hydration.[85]
	Conjunctivitis retinal hemorrhage	Occurs less often than vision. The conjunctivitis may be associated with development of Stevens–Johnson syndrome or an allergic reaction[85]

Antilipemic Agents		
Lovastatin	Cataracts	The crystalline lenses of hypercholesterolemic patients were assessed before and after 48 weeks of treatment with lovastatin 20–80 mg/day. Statistical analyses of the distribution of cortical, nuclear, and subcapsular opacities at 48 weeks showed no significant differences between placebo-treated and lovastatin-treated groups. Visual acuity assessments also were not significantly different among the groups[100]
Antineoplastic Agents		
Busulfan	Cataracts	Reported with high dosages.[85]
Carmustine	Arterial narrowing Nerve fiber layer infarcts Intraretinal hemorrhages	These ocular side effects are not well established. Evidence of delayed bilateral ocular toxicity developed in 2 of 50 patients treated with high-dose IV carmustine (800 mg/m^2). Symptoms of ocular toxicity became evident 4 weeks after IV treatment. Evidence of delayed ocular toxicity (mean onset 6 weeks) ipsilateral to the site of infusion developed in 7 of 10 patients treated with intra-arterial carotid doses of carmustine to a cumulative minimum of 450 mg/m^2 in two treatments[101]
Cytarabine	Keratoconjunctivitis Ocular burning Photophobia Blurred vision	Corneal toxicity and conjunctivitis have been reported with high-dose (3 g/m^2) therapy[102]
Doxorubicin	Conjunctivitis	May last for several days after treatment[85]
	Excessive tearing	
Erlotinib	Trichomegaly and ocular irritation	

Fluorouracil	Ocular irritation Lacrimation	Reversible and seldom interfere with continued therapy[85]
Tamoxifen	Corneal opacities Decreased vision Retinopathy	Generally occurs in patients receiving more than 1 year of treatment when a total dose exceeding 100 g has been taken[85]
Vinca alkaloids (especially vincristine)	Extraocular muscle paresis (EMP) Ptosis	The onset of EMP or paralysis may be seen as early as 2 weeks. Dose related. Most recover fully when drug is discontinued[85]
Barbiturates		
	Miosis Mydriasis Disturbances in ocular movement Ptosis	Most significant ocular side effects occur in chronic users or in toxic states. Pupillary responses are variable; miosis seen most frequently except in toxicity when mydriasis predominates. Nystagmus and weakness in extraocular muscles may be seen. Chronic abusers have a characteristic ptosis[85]
Bisphosphonates (Alendronate, Etidronate, Pamidronate, Risedronate)		
	Blurred vision, pain, photophobia, conjunctivitis, scleritis, uveitis	Adverse events more common with pamidronate. Scleritis and uveitis are of greatest concern. After persistent reduction in vision of sustained ocular pain, refer patient to an ophthalmologist. Ocular NSAID treatment may be of symptomatic benefit[90]
Calcium-Channel Blockers		
	Blurred vision Transient blindness	Primarily blurred vision; transient blindness at peak concentrations has been observed in several patients[103]
Corticosteroids		
	Cataracts	Posterior subcapsular cataracts have been associated with systemic corticosteroids in patients who have received >15 mg/day of prednisone or its equivalent daily for periods >1 year.[103,104] Rare reports of bilateral posterior subcapsular cataracts associated with nasal aerosol or inhalation of beclomethasone dipropionate have been received. Most patients had received therapy for >5 years, often in higher than the recommended dosage. Approximately 40% of patients also were receiving systemic corticosteroids.[106] (Also see Case 54-8, Question 1.)

	↑ Intraocular pressure (IOP)	More common with topical corticosteroids than with systemic therapy. Of little consequence in patients without preexisting glaucoma. Glaucoma patients should be monitored routinely if receiving systemic corticosteroids.[85] (See Case 54-8, Question 1.)
	Papilledema	Intracranial hypertension or pseudotumor cerebri from systemic corticosteroids has been well documented. The incidence appears to be greater in children than in adults; primarily associated with chronic therapy
Digitalis		
	Altered color vision,	Changes in color vision. A glare phenomenon and a snowy

	visual acuity	appearance in objects have been associated primarily with digitalis intoxication. In a small number of cases, reversible reduction in visual acuity has been noted. Also associated with changes in the visual fields[85]
	Decreased IOP	Digitalis derivatives can decrease IOP, but clinical use for glaucoma is not practical because the therapeutic systemic dose for this effect is very near the toxic dose[85]
Diuretics		
Carbonic anhydrase inhibitors	Myopia	Acute myopia that may last from 24 to 48 hours. Probably caused by an increase in the anteroposterior diameter of the lens, which may be reversible even if drug use is continued[85]
Thiazides	Myopia	Thiazide diuretics have been associated with acute myopia that may last from 24 to 48 hours.**85,86**
Estrogens		
Clomiphene	Blurred vision Mydriasis Visual field changes Visual sensations	5%–10% experience ocular side effects. Blurred vision is the most common effect, although visual sensations such as flashing lights, distortion of images, and various colored lights (primarily silver) may occur[85]
Oral contraceptives (OCs)	Optic neuritis Pseudotumor cerebri Retrobulbar neuritis	Quite rare. In patients with retinal vascular abnormalities, use of OCs is questionable. Numerous other possible ocular side effects are associated with these agents, and further documentation is required[85]
Hypouricemics		
Allopurinol	Cataracts	Conflicting reports have suggested allopurinol may be associated with anterior and posterior lens capsule changes and with anterior subcapsular vacuoles; 42 cases of cataracts have been reported; these have been observed primarily in age groups in whom normal lens aging changes would not be expected. No cause-and-effect relationship has been proven[85,107]
Immune Modulators		
Imatinib	Visual deficits	Ocular symptoms include blurred vision, conjunctivitis, dry eyes, epiphora, and periorbital edema. The latter occurs in up to 74% of treated patients[108]
Interleukin 2	Visual deficits	Interleukin 2 visual complications have occurred during the first or second treatment cycle, usually within 5–6 days of initiation of therapy. Ocular symptoms included diplopia, binocular negative scotomas (isolated areas of varying size and shape in which vision is absent or depressed; these are not perceived ordinarily, but would be apparent on completion of a visual field examination), and palinopsia (abnormal recurring visual imagery). In most cases, treatment was continued for the entire planned duration of therapy. Symptoms resolved after discontinuation[109]
Phenothiazines		
Chlorpromazine	Deposits on the lens	Rare when total dose <0.5 kg. Visible after a total dose of 1 kg in most cases; incidence may increase to 90% after ≥2.5 kg. Usually, deposits do not affect vision appreciably. The cornea and

		conjunctiva may be affected after the lens shows pigment changes[85]
	Retinal pigment deposits	The number of reported cases is small; further documentation is necessary[85]
Thioridazine	Pigmentary retinopathy	Primarily associated with maximal daily dosages or average doses >1,000 mg. Daily dosages up to 600 mg are relatively safe; 600–800 mg is uncertain, but rarely suspect. If >800 mg/day is used, periodic ophthalmoscopic examinations may uncover problems before visual acuity is compromised[85]

Therapy for Erectile Dysfunction		
Sildenafil Tadalafil Vardenafil α-Blockers	Changes in color or light perception, blurred vision, conjunctival hyperemia, ocular pain, photophobia	Color vision alterations are mild to moderate. Blurred vision does not impair visual acuity. Visual alterations usually subside within 4 hours after the dose.[110–112] Ocular adverse effects are uncommon, dose dependent, and fully reversible to date. Incidence is not related to age, but is related to blood concentration. Peak visual effects usually occur within 60 minutes after ingestion[90]
Alfuzosin	Visual defects	Amblyopia, blurred vision, and floppy iris have been reported[113]
Tamsulosin	Floppy iris	Approximately 3% of patients taking tamsulosin for benign prostatic hyperplasia (BPH) experience floppy iris during cataract surgery. Modification of the surgical procedure usually results in successful surgery[114]

CNS, central nervous system; ENT, ear, nose, and throat; NSAID, nonsteroidal anti-inflammatory drug.

OCULAR EMERGENCIES

Chemical Burns

CASE 54-4

QUESTION 1: S.J., a 24-year-old construction worker, has splashed an unidentified chemical in his eyes and runs into a nearby pharmacy complaining of burning in both eyes. Should the pharmacist attempt to treat S.J. or refer him to the emergency department?

Chemical burns require immediate attention. The immediate treatment is copious irrigation using the most accessible source of water (e.g., shower, faucet, drinking fountain, hose, bathtub). After at least 5 minutes of initial irrigation, S.J. should be taken immediately to the emergency department. A water-soaked towel or cloth should be kept on his eyes during transport.

Other Ocular Emergencies

When healthcare professionals are approached by patients with acute ocular emergencies (e.g., chemical burns, corneal trauma, corneal ulcers, acute angle-closure glaucoma), patients require immediate treatment and should be referred to an ophthalmologist if the practitioner has even the slightest doubt about appropriate therapy. It is difficult to effectively evaluate the severity of ocular disorders without the benefit of a thorough ophthalmologic workup and specialized training. In situations of corneal trauma from abrasion or foreign bodies, the patient often complains of a gritty, scratchy feeling and can be aware of a foreign body's presence. The corneal tissue is an excellent culture medium for bacteria (e.g., Pseudomonas aeruginosa), and therapy should be initiated as soon as possible to avoid corneal perforation and possible blindness.[1] Signs and symptoms of acute angle-closure glaucoma are reviewed in Case 54-2, Question 1.

Gonococcal conjunctivitis is an ocular emergency, and patients should be referred immediately to an ophthalmologist to minimize the potential of corneal perforation.[1] These patients, who can present with symptoms of red, tender, swollen eyelids with exophthalmos and mild pain, may be suffering from orbital cellulitis or endophthalmitis, which require immediate treatment with systemic antibiotics. Conjunctivitis of other origins (see Acute Bacterial Conjunctivitis [Pinkeye] and Allergic Conjunctivitis sections) generally is not an ocular emergency.

Any loss of vision (whether sudden, complete, or transient), flashes of light, pain, or photophobia can signify potentially damaging ocular disorders (e.g., retinal artery occlusion, optic neuritis, amaurosis fugax, retinal detachment), and an ophthalmologist should evaluate the patient as soon as possible. Referral also is recommended for patients with blurred vision, pupil disorders, diplopia, nystagmus, or ocular hemorrhage.

COMMON OCULAR DISORDERS

Stye (Hordeolum)

Sties are infections of the hair follicles or sebaceous glands of the eyelids. The most common infecting organism is Staphylococcus aureus. Treatment consists of hot, moist compresses and topical antibiotics (e.g., sulfacetamide). Over-the-counter products should not be recommended. An ophthalmologist should evaluate sties that do not respond to warm compresses within a few days.

Conjunctivitis

Conjunctivitis, a common external eye problem that involves inflammation of the conjunctiva, usually is associated with symptoms of a diffusely reddened eye with purulent or serous discharge accompanied by itching, smarting, stinging, or a scratching foreign-body sensation. Patients with pain, decreased vision, unequal distribution of redness, irregular pupils, or opacity should be referred immediately to an ophthalmologist because these are signs of more serious eye disease.

Conjunctivitis can be bacterial, fungal, parasitic, viral, or allergic in origin. Most cases of bacterial conjunctivitis are caused by Staphylococcus. aureus, Streptococcus pneumoniae, Haemophilus influenzae and Moraxella catarrhalis, although a number of other organisms may be responsible. The infection usually starts in one eye and is spread to the other by the hands. It also may be spread to other persons. Unlike bacterial conjunctivitis, corneal infections can obliterate vision rapidly; therefore, accurate diagnosis is important.

ACUTE BACTERIAL CONJUNCTIVITIS (PINKEYE)

CASE 54-5

QUESTION 1: L.T. is a 6-year-old boy with diffuse bilateral conjunctival redness that has been present for 2 days. A crusting discharge is deposited on his lashes and the corners of his eyes. His vision is normal, and his pupils are round and equal. The diagnosis of acute bacterial conjunctivitis is made, and sodium sulfacetamide 10% ophthalmic drops, two drops in both eyes every 2 hours while awake, are prescribed. What other measures should be used? What instructions should his caregivers receive?

Although treatment of typical bacterial conjunctivitis such as this is empirical, a culture should be obtained. Other ophthalmic antibiotic drops or ointments, such as neomycin-polymyxin-B-gramicidin combination (Neosporin) or polymyxin-trimethoprim (Polytrim), also are used in these situations. Although other antimicrobials, such as the ocular quinolones, may be used for bacterial conjunctivitis, these agents should be reserved as second-line therapies because of cost and the potential development of resistance. Proper management of this infection also includes mechanical cleaning of the eyelids and hygienic measures that prevent spreading the infection to other children. The deposits should be removed as often as possible with moist cotton swabs or cotton-tipped applicators. A mild baby shampoo can be used to moisten the applicator. Firm adherent crusts may be softened with warm, moist compresses. Because this material is infectious, it should be disposed of in a sanitary fashion. The common use of washcloths by several individuals will spread bacterial conjunctivitis.

ALLERGIC CONJUNCTIVITIS

CASE 54-6

QUESTION 1: N.V., a 10-year-old girl, has experienced redness in both eyes accompanied by "hay fever" for the past 2 months (June and July). There is no crusting on her eyelids, and her vision is normal; she rubs her eyes often because they itch. What treatment is best for N.V.'s allergic conjunctivitis?

Topical vasoconstrictors (e.g., naphazoline, tetrahydrozoline) with or without antihistamines (e.g., antazoline, pheniramine) may be used to treat hyperemia, but they should not be used excessively because rebound congestion can occur. Use of topical vasoconstrictors for longer than 72 hours is not recommended owing to the potential for rebound congestion and masking of more serious ocular inflammatory conditions. Antihistamine tablets or syrup can provide considerable, but temporary, relief. Several ophthalmic histamine H_1-receptor antagonists are effective in the treatment of allergic conjunctivitis. Levocabastine 0.05% is administered BID to QID, olopatadine 0.1% BID (separating doses by 6–8 hours) or 0.2% once daily, emedastine 0.05% QID, ketotifen 0.025% BID to QID, bepotastine 1.5% BID, and alcaftadine 0.25% once daily.[115–117] Ketotifen, olopatadine, azelastine, epinastine, and alcaftadine exhibit both antihistamine and mast cell stabilizing effects. Emedastine was more efficacious than levocabastine when used BID for 6 weeks in adult and pediatric patients with seasonal allergic conjunctivitis.[118] Olopatadine provided superior efficacy and a more rapid resolution of the signs and symptoms of allergic conjunctivitis when compared with ketotifen in a small trial involving adult patients.[119] Azelastine has a slightly quicker onset of therapeutic effect when compared with olopatadine and placebo.[120] Bepotastine 1.5% BID provided better relief of evening ocular and nasal symptoms than olopatadine 0.2% administered once daily for 14 days.[121] Alcaftadine 0.25% and olopatadine 0.2% administered once daily provided relief of ocular itching at 16 and 24 hours postinstallation with alcaftadine also providing significant relief from chemosis.[122] Information to date is insufficient to definitively recommend one of these products as superior to the others. The ideal treatment would be removal of the allergen, but this usually is impossible when the conjunctivitis is secondary to seasonal allergies. Topical corticosteroids provide dramatic relief, but their use must be limited because of potential adverse effects (see Ophthalmic Corticosteroids section).

Cromolyn sodium ophthalmic, a drug that inhibits the release of histamine in response to antigen, may be effective as an alternative for patients who fail to respond to more conservative measures. Lodoxamide, pemirolast, and nedocromil have a similar mechanism of action to cromolyn sodium ophthalmic, but these agents also decrease chemotaxis and activation of eosinophils. In comparative studies, lodoxamide tromethamine 0.1% is at least as effective as cromolyn sodium ophthalmic 2% to 4% in treating allergic ocular disorders, including vernal keratoconjunctivitis.[123,124] Patients in these studies demonstrated more rapid and greater response when treated with lodoxamide, one drop QID. In a 2-week crossover study of nedocromil and olopatadine involving 28 patients of 7 years of age and older, patient acceptance of nedocromil BID was better than for olopatadine BID, but treatment outcomes were essentially equal.[124,125]

Corneal Ulcers

CASE 54-7

QUESTION 1: T.S. presents with a diagnosis of bacterial corneal ulcer in the right eye and prescriptions for "fortified gentamicin" and cefazolin eyedrops, which are not commercially available. What is the rationale for this therapy, and how can the patient obtain it?

The initial choice of therapy for bacterial corneal ulcers commonly is based on a Gram stain and clinical impression of the severity of the ulcer. Single or combination antimicrobial therapy can be prescribed. Although commercial antimicrobial ophthalmic formulations are available, the antimicrobial concentrations in these products might be inadequate to effectively treat bacterial corneal ulcers.[126,127]

Topical antimicrobials for the treatment of bacterial corneal ulcers can be prepared from parenteral antimicrobials or by the addition of parenteral antimicrobials to "fortify" commercially available products. Commonly prescribed products include bacitracin 5,000 to 10,000 units/mL, cefazolin 33 to 100 mg/mL, gentamicin or tobramycin 9.1 to 13.6 mg/mL, and vancomycin 25 to 50 mg/mL. Fortified gentamicin has been prepared by adding 80 mg of parenteral gentamicin to the commercially available gentamicin ophthalmic solution. The final concentration of this solution is 13.6 mg/mL. Cefazolin ophthalmic solution is prepared by reconstituting 500 mg parenteral cefazolin with 2 mL of sterile normal saline. Two milliliters of artificial tears solution are removed from a commercially available 15-mL bottle and replaced with the 2-mL reconstituted cefazolin solution (resulting in a final cefazolin concentration of 33 mg/mL). Therapy initially can be administered as frequently as every 15 to 30 minutes with extension of intervals as the ulcer resolves.[128] The preparation of extemporaneously compounded ophthalmic products must adhere to established federal and state agency guidelines, and must address quality control concerns (e.g., pH, tonicity, sterility, particulate matter). The formulation of sterile products should not be undertaken without due consideration of well-established practice standards. In most situations, these products are prepared within a laminar flow hood.

OPHTHALMIC CORTICOSTEROIDS

Comparison of Preparations and Clinical Use

CASE 54-8

QUESTION 1: S.S. has undergone cataract extraction from his left eye. Prednisolone acetate 1% administered 4 times daily has been prescribed. Is prednisolone acetate an appropriate choice?

The topical ophthalmic corticosteroid preparations are described in Table 54-4. The salt form affects the ability of the preparation to penetrate the cornea. For example, biphasic salts penetrate the intact cornea better than water-soluble salts. The ability of a formulation to penetrate the cornea, however, does not indicate increased therapeutic effectiveness. Prednisolone acetate 1% and fluorometholone acetate 0.1% have the best anti-inflammatory effects.[129–131] The most commonly prescribed ophthalmic corticosteroid is prednisolone acetate because of its availability in generic form and generally lower cost.

Table 54-4

Ophthalmic Corticosteroids

Low Potency	Intermediate Potency	High Potency
Dexamethasone 0.05% (Decadron Phosphate)	Clobetasone 0.1%[a]	Clobetasone 0.5%[a]
Dexamethasone 0.1% (Decadron Phosphate)	Dexamethasone alcohol 0.1% (Maxidex)	Fluorometholone acetate 0.1% (Flarex)
Medrysone 1% (HMS)	Fluorometholone 0.1% (FML) Fluorometholone 0.25% (FML Forte) Loteprednol 0.2% (Lotemax) Loteprednol 0.5% (Alrex) Prednisolone acetate 0.12% (Pred Mild) Prednisolone sodium phosphate 0.125% (Inflamase Mild) Prednisolone sodium phosphate 1% (Inflamase Forte)	Prednisolone acetate 1% (Pred Forte) Rimexolone 1% (Vexol)

[a] Not commercially available in the United States.

Topical ophthalmic corticosteroids are used for a variety of conditions associated with inflammation of the conjunctiva, cornea, and within the anterior segment of the eye. They are generally contraindicated in individuals with ocular varicella, vaccinia, herpes simplex, and mycobacterial infections.

Adverse Effects

INCREASED INTRAOCULAR PRESSURE

CASE 54-8, QUESTION 2: S.S. continued using topical prednisolone acetate 1%, one drop in the left eye QID for 8 weeks. Before therapy, the IOPs in both eyes were 16 mm Hg, but on the last follow-up visit, his IOP was 16 mm Hg in the right eye and 26 mm Hg in the left eye. Assess these observations.

S.S.'s elevated IOP could be related to topical steroid therapy. In one study, the ophthalmic administration of corticosteroid preparations (Table 54-5) increased IOP in three genetically distinct subgroups.[104,105,132] Fluorometholone acetate increased IOP by more than 10 mm Hg in known steroid responders in 29.5 days (median), whereas dexamethasone did the same in 22.7 days (median).[133] In a retrospective follow-up, 13% of high-corticosteroid responders developed POAG and 63.8% developed ocular hypertension. No low responders developed POAG, and only 2.4% developed ocular hypertension.[133] Although corticosteroid-induced increases in IOP are associated most frequently with topical ophthalmic preparations, systemic corticosteroids may cause a similar response, although the magnitude is somewhat less.[134] The risk for corticosteroid-induced ocular hypertension is greater in patients with high myopia, diabetes mellitus, or connective tissue disease (particularly rheumatoid arthritis).

Topical corticosteroids exert their effects by decreasing aqueous humor outflow, whereas systemic corticosteroids may increase aqueous humor production.[134] The effects on IOP apparently are unrelated to the ability of the corticosteroid to penetrate the cornea. Dexamethasone has been associated with the greatest IOP increase.[135] Fluorometholone, medrysone, rimexolone, and loteprednol have been associated with lower, although sometimes significant, increases in IOP.[136–138] The pressure response often is reversible when the offending agent is discontinued. In subjects with prolonged IOP elevation, glaucomatous field defects are more likely to develop in corticosteroid-responsive patients.[139]

CATARACTS

CASE 54-9

QUESTION 1: G.A., who had asthma, has been taking prednisone 10 mg/day for 1 year. A routine ophthalmic examination revealed early cataract formation. Why could this be related to the prednisone?

Systemic and topical ophthalmic corticosteroids have been associated with the development of cataracts. About 23% of patients treated with 10 to 16 mg/day of prednisone orally (or its equivalent dose) for 1 year or more developed posterior subcapsular cataracts (PSC).[140,141] The estimated occurrence of PSC in patients treated with more than 16 mg/day of prednisone for more than a year increased to more than 70% during the same period. Patients receiving less than 10 mg/day prednisone or its equivalent are unlikely to develop PSC, although some contend that the concept of a “safe” dosage should be abandoned because of variable patient sensitivity to this side effect.[142] As illustrated by G.A., the cataracts cause few subjective complaints and little measurable decrease in visual acuity. Although systemic corticosteroids primarily are implicated, use of topical corticosteroids also has been associated with PSC formation.[143] Patients treated with alternate-day dosing of oral corticosteroids may be at lower risk for PSC formation.[144] Any patient receiving long-term corticosteroids should receive routine ophthalmic follow-up.

Table 54-5

Intraocular Pressure Response to Topical Steroids in Random Populations

Author	Parameter of Response	No. of Subjects	Low	Medium	High	Mean
Armaly[105]	Increase of pressure in eye medicated with 0.1% dexamethasone	80	<5 mm Hg 66%	6–15 mm Hg 29%	16 mm Hg 5%	5.5 mm Hg
Becker et al.[132]	Final pressure in eye medicated for 6 weeks with 0.1% betamethasone	50	<19 mm Hg 70%	20–30 mm Hg 26%	32 mm Hg 4%	17.0 mm Hg
	Time to maximal response		2 weeks	4 weeks	4 weeks	

SYSTEMIC SIDE EFFECTS FROM OPHTHALMIC MEDICATION

CASE 54-10

QUESTION 1: J.F., a 62-year-old woman, received one drop of phenylephrine 10% in each eye to dilate the pupils. Shortly after administration, her blood pressure increased to 210/130 mm Hg for 5 minutes, and she became confused. How common is this type of reaction in patients receiving topical phenylephrine? What other topical ophthalmic medications have been associated with systemic effects?

In 33 cases, possible adverse effects have been associated with topical phenylephrine 10%.[145] In a double-blind study, no statistically significant differences were observed in blood pressure or pulse rate between experimental and control groups when phenylephrine 10% or tropicamide (Mydriacyl) 1% was administered to 150 patients.[146] Nevertheless, care should be taken when phenylephrine 10% is administered in patients with hypertension or cardiac abnormalities in whom systemic absorption could be hazardous. No similar reports have been associated with topical use of phenylephrine 2.5%.

In addition to the systemic effects from topical administration of cholinergic agents, epinephrine, and timolol that were previously described, topical atropine, cyclopentolate (Cyclogyl), and scopolamine have been associated with psychosis.[147–149] Fatalities have been associated with topical atropine,[150] ataxia has occurred with topical homatropine, and one case of unconsciousness with tropicamide was reported.[151]

Topical chloramphenicol-polymyxin-B sulfate ophthalmic ointment has been associated with bone marrow aplasia after intermittent use for 4 months.[152] A cushingoid reaction has been reported in a 30-month-old baby girl treated with dexamethasone alcohol (Maxidex) 4 times a day in both eyes for 14 months.[153]

The administration of ophthalmic prostaglandins and PGAs are associated with systemic side effects (Table 54-1).

OCULAR NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

CASE 54-11

QUESTION 1: W.A. is scheduled to undergo cataract extraction with implantation of an intraocular lens. Preoperative orders include administration of flurbiprofen 0.03% to inhibit intraoperative miosis. The formulary includes only diclofenac 0.1%. Is this a suitable alternative to flurbiprofen?

Commercially available ophthalmic nonsteroidal anti-inflammatory drugs (e.g., bromfenac, diclofenac, flurbiprofen, ketorolac and nepafenac) share a similar mechanism of action involving inhibition of prostaglandin synthesis and reduction of prostaglandin-mediated ocular effects.[154] Minor clinical differences, which probably are insignificant, exist and approved indications differ (Table 54-6).[155–162] These agents are generally well tolerated, but they can cause transient burning and stinging on instillation. Diclofenac is not approved for prevention of intraoperative miosis, but various dosage regimens have been reported as effective for this use.

OCULAR HERPES SIMPLEX VIRUS INFECTIONS

CASE 54-12

QUESTION 1: P.B., a 34-year-old man, presents with a 2-week history of a red, irritated left eye with watery discharge. Recently, vision in his left eye became blurred, and he complained of light sensitivity. A slit-lamp examination with rose bengal stain revealed a multibranched corneal epithelial defect. This dendritic ulcer is the hallmark of ocular herpes simplex (type 1) infection. What is the therapy of choice for P.B.?

Ocular herpes is common and can be caused by herpes simplex virus or, less commonly, by the varicella-zoster virus (herpes zoster ophthalmicus). Herpes simplex of the eye typically affects the eyelids, conjunctiva, and cornea, and patients often present with symptoms of pain, tearing, eye redness, sensitivity to light, and irritation or a foreign body sensation. When herpes affects the epithelium of the cornea (herpes keratitis), it generally heals without scarring. Occasionally, deeper layers of the cornea are affected (stromal keratitis), and scarring can lead to blindness. Trifluridine is the drug of choice for P.B.

TRIFLURIDINE

In vitro, the mechanism of action of trifluridine is similar to that of idoxuridine (IDU). Trifluridine also inhibits thymidylate synthase, an enzyme required for DNA synthesis.

For the treatment of ocular herpes, one drop of trifluridine 1% ophthalmic solution should be instilled into the affected eye every 2 hours while awake with a maximal daily dose of nine drops. After re-epithelialization, application of trifluridine should be continued for an additional 7 days at a reduced dosage of one drop every 4 hours while awake with a minimum of five drops daily. Continuous administration for periods exceeding 21 days is not recommended because of potential ocular toxicity.

Approximately 96% of treated herpetic corneal ulcers heal within 2 weeks.[163] Therapeutic levels of trifluridine can be found in the aqueous humor after topical administration of a 1% solution, enhancing its possible effectiveness in the treatment of stromal keratitis and uveitis. Trifluridine also is effective in treating herpes simplex virus infections resistant to IDU or vidarabine.

Despite the apparent superiority of trifluridine compared with its antiviral predecessors (IDU, vidarabine), it is not without disadvantages. Trifluridine is activated by uninfected corneal cells and is incorporated into cellular as well as viral DNA. Punctate lesions in the corneal epithelium are clinical manifestations of trifluridine cytotoxicity.[164] However, these effects seem to occur less often with trifluridine than with IDU and vidarabine.

ACYCLOVIR

Acyclovir in in vitro plaque inhibition assays has 5 to 10 times the activity of IDU and trifluridine and more than 100 times the activity of vidarabine against strains of type 1 and type 2 herpes simplex virus.[165] Acyclovir's apparent superiority lies in its lack of toxicity to normal host cells. In rabbits (rabbit eyes are similar to human eyes), acyclovir 3% ointment healed established herpes simplex epithelial ulcerations at a faster rate and eliminated the virus more effectively than 0.5% IDU and 3% vidarabine ointments.[166] In humans, ulcerative corneal epithelial lesions appear to respond similarly to acyclovir and IDU.[166] In comparison with IDU, the topical application of acyclovir or trifluridine resulted in a greater proportion of subjects healing within 1 week and neither was superior for the treatment of dendritic epithelial keratosis.[167] The dose usually is a 1-cm ribbon of ointment instilled 5 times a day at 4-hour intervals for 14 days or for at least 3 days after healing is completed, whichever is shorter. Detailed dosing instructions are available in product literature of specific manufacturers, and brief reviews of acyclovir and acyclovir resistance are presented in 77, Opportunistic Infections in HIV-Infected Patients, and Chapter 79, Viral Infections.

Table 54-6

Ocular Nonsteroidal Anti-Inflammatory Drugs

Indication	Drug/Approval Status for Indication	Dosage(s)
Inhibition of intraoperative miosis	Diclofenac 0.1% (Voltaren, U)[155]	Three reported regimens; 1 drop every 15–30 minutes for four doses; 1 drop TID for 2 preoperative days; 1 drop at 2 hours, 1 hour, and 15 minutes before surgery
	Flurbiprofen 0.03% (Ocufen, A)[156]	One drop every 30 minutes for 2 hours before surgery
	Ketorolac 0.5% (Acular, U)	One drop every 15 minutes beginning 1 hour before surgery
Anti-inflammatory after cataract surgery	Bromfenac 0.09% (Xibrom, A)	One drop BID beginning 24 hours after surgery and continuing through the 2 weeks of the postoperative period
	Diclofenac 0.1% (A)[157] Nepavanac 0.1% (Nevanac, A)	One drop BID to QID, including 24 hours preoperative administration. One drop TID beginning 1 day before cataract surgery, continued on the day of surgery and through the first 2 weeks of the postoperative period (Nevanac prescribing information. Alcon Laboratories, November 2006)
	Ketorolac 0.5% (A)[158]	One drop TID, including 24 hours preoperative administration
Prevention/treatment of cystoid macular edema	Diclofenac 0.1% (U)[159]	Two drops 5 times preoperatively followed by one drop 3–5 times daily
	Ketorolac 0.5% (U)[158,160]	One drop TID or QID, including 24 hours preoperative administration
Ocular inflammatory conditions (iritis, iridocyclitis, episcleritis)	Diclofenac 0.1% (U)	One drop QID
Seasonal allergic/vernal conjunctivitis	Bromfenac 0.1% (U)	One drop BID
	Diclofenac 0.1% (U)	One drop every 2 hours for 48 hours; then QID
	Ketorolac 0.5% (A)[161,162]	One drop QID

A, approved use; BID, twice daily; QID, 4 times a day; TID, 3 times a day; U, unapproved use.

OTHER DRUGS

Ganciclovir 0.05% and 0.15% gel have been shown to be equivalent to 3% acyclovir ointment in the treatment of superficial herpes simplex keratitis.[168] Cidofovir 1%

ointment administered BID was equivalent to trifluridine administered 5 times daily in the rabbit model.[169] Cidofovir was more efficacious than 3% penciclovir ointment administered 2 or 4 times a day.[169]

AGE-RELATED MACULAR DEGENERATION

CASE 54-13

QUESTION 1: E.A., a 77-year-old woman, informs you she read information from the Internet and she thinks her symptoms of blurred vision and the need for a bright light to read are consistent with age-related macular degeneration. She asks which of the available medicines would be best for her.

Age-related macular degeneration is the leading cause of blindness in Americans of European descent who are 55 years of age and older.[170] There are two forms of macular degeneration, wet and dry. The dry form, affecting about 85% of patients, develops as a result of the breakdown of light-sensitive cells in the macula.[171] The most common symptom associated with dry macular degeneration is blurred vision. In this situation, details (e.g., faces, words in a book) are seen less clearly. Wet macular degeneration occurs in 15% of patients and is the more serious form, responsible for the most cases of vision loss. One of the first symptoms of wet macular degeneration is the appearance of straight lines as wavy. Wet macular degeneration is associated with abnormal growth of blood vessels behind the retina, known as choroidal neovascularization. Vascular endothelial growth factor (VEGF) is associated with the pathogenesis of choroidal

---

neovascularization. VEGF may stimulate neovascularization by influencing endothelial cell proliferation, vascular permeability, and ocular inflammation.[172] The correlation between VEGF and wet age-related macular degeneration has led to interest in VEGF inhibitors (pegaptanib, bevacizumab, ranibizumab) as treatment agents.

PEGAPTANIB

Pegaptanib inhibits angiogenesis, decreases permeability of the vascular bed, and decreases inflammation. The efficacy of pegaptanib has been evaluated in two concurrent, prospective, randomized, double-blind trials involving 1,208 patients. A total of 1,190 patients received at least one study treatment, with four subjects being excluded from the efficacy analysis owing to insufficient assessment of visual acuity at baseline. A combined analysis of 1,186 patients at week 54 showed a statistically significant reduction in vision loss associated with pegaptanib, realized as early as week 6 and continued through week 54.[173] The FDA-approved dose of pegaptanib (0.3 mg intravenously every 6 weeks) is no less effective than 1- or 3-mg doses, and the most serious injection-related adverse events were endophthalmitis (12 patients), traumatic injury to the lens (five patients), and retinal detachment (six patients).[173] Patients should be monitored for elevations in IOP after injection; increases in IOP have been seen within 30 minutes of injection and should be monitored within 2 to 7 days after the injection.

BEVACIZUMAB

Bevacizumab is a recombinant humanized monoclonal immunoglobulin G1 antibody approved for intravenous use for first- or second-line treatment of metastatic colorectal cancer. This product has been used off-label via the intravenous and intravitreal routes for the treatment of neovascular ocular disorders in more than 3,500 patients.[172] Intravenous bevacizumab 5 mg/kg was administered every 2 weeks for two or three infusions in 18 patients for whom 12- and 24-week results on subfoveal choroidal neovascularization were published separately. Therapy was associated with improved visual acuity. No serious ocular or systemic adverse effects were noted, although a statistically significant increase in blood pressure was noted at week 3. Nineteen published, uncontrolled case series studies have evaluated the use of intravitreal bevacizumab for the treatment of wet macular degeneration as well as other conditions associated with neovascularization. The most common intravitreal dose was 1.25 mg, usually administered every 4 to 6 weeks. Doses could be repeated if signs of progression occurred. The longest period of study for intravitreal use was 1 year. The majority of patients in these open-label trials were followed up for 3 months. Mean visual acuity improved, and no serious ocular effects were noted.

RANIBIZUMAB

Ranibizumab is a Fab fragment of bevacizumab approved in June 2006 for the intravitreal treatment of wet macular degeneration. Ranibizumab is approximately one-third the size of bevacizumab. Its size may facilitate retinal penetration after intravitreal injection. Ranibizumab has a shorter-systemic half-life and higher VEGF binding affinity than bevacizumab, but bevacizumab has two binding sites per molecule versus one for ranibizumab. The clinical relevance of these pharmacokinetic and pharmacodynamic differences is not known.[172] The recommended dosage of ranibizumab is 0.5 mg via the intravitreal route administered every 4 weeks. This treatment has been associated with maintenance or improvement of vision for 12 to 24 months.[173] The primary ocular side effects associated with ranibizumab administration include conjunctival hemorrhage, eye pain, and increased IOP.

Bevacizumab is significantly less expensive than ranibizumab. Similar efficacy associated with lower cost may lead to increased use for neovascular age-related macular degeneration. The National Eye Institute has initiated the Comparisons of Age-Related Macular Degeneration Treatments Trials, a multicenter, randomized clinical trial of ranibizumab and bevacizumab in the treatment of neovascular age-related macular degeneration.[174]

AFLIBERCEPT

In September 2012, aflibercept became the second VEGF inhibitor approved for treatment of macular edema secondary to choroidal vein retinal occlusion (CRVO). Preliminary results from the ongoing COPERNICUS and GALILEO trials proved the efficacy of this medication in treating macular edema secondary to CRVO. Of the combined 358 patients studied in COPERNICUS and GALILEO, 56% and 60%, respectively, of the patients receiving aflibercept 2 mg monthly achieved at least a 15-letter improvement in best-corrected visual acuity (BCVA) from baseline over 6 months compared with just 12% and 22% in the control group ($p < 0.01$ for both). Additionally, in COPERNICUS and GALILEO, patients achieved a 21.3- and 14.7-letter improvement, respectively, in BCVA compared with placebo ($p < 0.01$ for both).[175]

While efficacy and safety appear similar to other anti-VEGF treatments, the higher potency, binding affinity, and duration of action make aflibercept an appealing new option.

Pain and Its Management

Lee A. Kral and Virginia L. Ghafoor

	CORE PRINCIPLES	CHAPTER CASES
1	Perioperative analgesia utilizes nerve blocks via peripheral or spinal local anesthetic delivery. A preoperative pain assessment may identify a history of uncontrolled postsurgical pain, analgesic intolerance or contraindication, risks and benefits of regional anesthesia, and presence of preoperative pain or anxiety.	**Case 55-1 (Questions 1–3)**
2	Multimodal analgesia is a strategy that utilizes a combination of different analgesic modalities to achieve better postoperative pain management and a subsequent reduction in adverse effects. The additive and synergistic effects between different classes of analgesics allow for a reduction in the doses of individual medications while achieving similar or better pain control.	**Case 55-2 (Questions 1–3)**
3	Low back pain is a very common chronic pain condition. It is complex, often involving physical and emotional factors. Patients may have musculoskeletal, neuropathic, and/or central pain that needs to be assessed, as well as comorbidities.	**Case 55-3 (Questions 1, 2)**
4	Chronic pain management requires multimodal therapies, both pharmacologic and nonpharmacologic. Many factors affect analgesic selection, including comorbidities, available routes of administration, and cost.	**Case 55-3 (Questions 3–7)**
5	Neuropathic pain may be caused by injury to peripheral nerves or to the central nervous system. Neuropathic pain is treated with analgesic antidepressants and anticonvulsants. Peripheral or localized nerve pain may be treated with topical agents.	**Case 55-4 (Questions 1, 2)**
6	Elderly patients and patients with multiple comorbidities are at high risk for adverse effects. Pharmacokinetic and pharmacodynamic drug interactions must be considered with the use of anticonvulsants and antidepressants.	**Case 55-4 (Questions 3, 4)**
7	Central neuropathic pain may present with peripheral symptoms that are localized or generalized. Pharmacotherapy provides only modest relief. Central poststroke pain is commonly multifactorial, including neuropathic pain and nociceptive pain. Central pain may respond to traditional neuropathic pain therapies. NSAIDs are ineffective. Comorbidities and	**Case 55-5 (Questions 1, 2)**

drug interactions must be considered.	
⑧ Functional pain does not have a clear pathophysiology. Comorbid mental health issues and psychosocial stressors complicate chronic pain management. Analgesic antidepressants and anticonvulsants, in conjunction with cognitive behavioral therapies, are recommended for management of functional pain syndromes (FPSs).	**Case 55-6 (Questions 1, 2)**
⑨ Opioid therapy requires effective risk assessment to avoid medication abuse, misuse, and diversion. Monitoring recommendations should include use of written opioid agreements, urine drug testing, opioid risk screening tools, and electronic prescription monitoring program records.	**Case 55-7 (Questions 1–6)**
⑩ Cancer pain may result from one or more causes related to direct tumor involvement, cancer therapy, and psychological factors. Pain management involves assessment of the patient to determine the etiology of pain and development of a care plan to address pain and other symptom management.	**Case 55-8 (Question 1)**
⑪ Transdermal fentanyl and methadone are potent opioids commonly used in cancer pain management. Opioid conversion tables for fentanyl and methadone are different due to differences in pharmacokinetics. Supplemental doses of short-acting opioids are recommended for breakthrough pain management.	**Case 55-8 (Questions 2–5)**
⑫ Opioid adverse effects including sedation, constipation, nausea, vomiting, itching, and respiratory depression should be addressed in the pain management plan. Complementary and alternative medicine therapies are widely used by patients in the management of cancer pain, dyspnea, and nausea and vomiting. Neuraxial opioid administration may be appropriate for patients with intolerable pain who cannot tolerate systemic opioid therapy.	**Case 55-8 (Questions 6–9)**

INCIDENCE, PREVALENCE, AND EPIDEMIOLOGY

Pain is defined as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.”[1] The ability to experience pain is critical for survival because it informs the body of real or potential injury (e.g., touching a hot stove). The body is then able to respond to the threat and protect itself from further injury (e.g., refraining from touching or removing the hand from the hot stove). Pain is a hallmark of many acute and chronic conditions. More than 80% of patients who undergo surgical procedures experience acute pain, 75% of which report the severity as moderate, severe, or extreme.[2,3] Chronic pain affects more than 25% of Americans over the age of 20 years.[4] Many people think that pain is a natural part of growing older, and up to 60% of people believe that pain is just something you have to live with.[5] However, nearly all cases of chronic pain begin as acute pain stemming from surgery, trauma, or illness.[6] The Institute of Medicine in 2011 estimated that $635 billion is spent annually on treatment of chronic pain conditions alone.[7] Back pain and osteoarthritis (OA) are among the top 5 chronic pain conditions associated with high healthcare costs and the prevalence continues to rise with the aging U.S. population. A study of Humana insurance utilization data for Medicare members from 2007 to 2011 found that annual costs were $327 million for OA and $218 million for back pain.[8] There are also gender, racial, and socioeconomic disparities that exist with chronic pain. Chronic pain is reported more often in women than in men, and in non-Hispanic white patients compared with other races and ethnicities.[4] Chronic pain is also more common in those whose income is 2 times less than the level of poverty. Pain is more complex than just physiology. It is a subjective experience, and sometimes the severity of pain does not appear to equal the extent of tissue damage. A person's perception of pain is affected by environmental, emotional, cultural, spiritual, and cognitive factors. Unrelieved chronic pain affects not only physical well-being but also a person's psychological and social well-being and relationships with loved ones. Recent estimates showed that musculoskeletal-related conditions with low back pain, neck pain, and knee OA ranked within the top 10 noncommunicable diseases for global disability-adjusted life years (i.e., years of life lost and years lived in disability).[9,10]

Factors that increase pain and suffering include sensory factors, cognitive factors, and emotional factors (Fig. 55-1). All are interrelated and illustrate the complex nature of chronic pain.

Pathophysiology

ASCENDING PATHWAY

Nociception, or the sensation of pain, is composed of four basic processes: transduction, transmission, modulation, and perception (Fig. 55-2). Transduction is the process by which noxious stimuli are translated into electrical signals at peripheral receptor sites (i.e., free nerve endings located throughout the skin, muscle, joints, fascia, and viscera). Normal sensory stimuli do not activate the pain signal, but if the stimulus is powerful enough to surpass the threshold for innocuous activation, the receptors become nociceptors (i.e., pain receptors). These sensory receptors target mechanical (crushing or pressure), chemical (endogenous or exogenous), or thermal (hot or cold) stimuli. Some nociceptors are polymodal, transducing more than one type of stimuli. One of these types of nociceptors is called the transient receptor potential (TRP). This family has a large number of members that are activated by the whole spectrum of thermal stimuli (very hot to very cold), as well as some mechanical and various chemical stimuli. Other receptors are “silent,” but are recruited if the stimulus is more intense or prolonged.

Nociceptors

Figure 55-2 Pain pathways. 5-HT, serotonin; NE, norepinephrine.

After stimulation of nociceptors, several processes occur. Proinflammatory mediators, including histamine, substance P, prostaglandins, bradykinins, and serotonin are released at the site of injury. Immune mediators are also released, including tumor necrosis factor, nerve growth factors, interleukins, and interferons.

These mediators sensitize the nociceptors, lowering the pain threshold in and around the injury (peripheral sensitization). The sensitized nociceptors may fire more frequently and erratically and are stimulated by much weaker stimuli (hyperalgesia). More frequent firing is correlated with an increase in pain intensity.

Transmission is the propagation of the electrical signal along primary afferent nerves, through the dorsal horn of the spinal cord to the central nervous system (CNS). Painful impulses are generated at the nociceptor, with voltage-gated sodium channels initiating the action potentials. Voltage-gated calcium channels are responsible for allowing calcium influx to the presynaptic terminal, causing neurotransmitter release. The message is then transmitted to the spinal cord via two primary afferent nerve types: myelinated A fibers and unmyelinated C fibers. The Aδ fibers are responsible for rapidly conducting impulses associated with thermal and mechanical stimuli. Transmission of signals along Aδ fibers results in sharp or stabbing sensations that alert the patient to an injury (also called “first pain”). This produces reflex signals, such as musculoskeletal withdrawal, to prevent further injury.

The smaller, unmyelinated C fibers respond to mechanical, thermal, and chemical stimuli but conduct impulses at a much slower rate compared with Aδ fibers. Transmission of electrical impulses via C fibers results in pain that is dull, aching, burning, and diffuse (called “second pain”). Prolonged stimulation of C fibers causes an additive effect on the perceived intensity of second pain, called windup.

At the level of the dorsal horn of the spinal cord, the primary afferents cause calcium release into the presynaptic terminal. This leads to release of excitatory amino acids (EAAs) like glutamate into the synapse (Fig. 55-3). C fibers also release peptides such as substance P, neurokinins, and calcitonin gene-related peptide (CGRP). The EAAs then stimulate the postsynaptic receptors and the electrical signals stimulate second-order neurons in the CNS. The postsynaptic α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionate (AMPA) receptors are sodium channel-mediated and are responsible for the first pain mentioned previously. N-methyl-D-aspartate (NMDA) receptor channels allow both sodium and calcium passage. Usually a magnesium ion holds the channels closed; however, when there is sustained firing from the primary afferents, the magnesium ion is displaced and the NMDA receptor is activated. This sensitizes the second-order neurons that will then discharge at a higher frequency. When sensitization occurs, the firing threshold is reduced, so even slightly painful stimuli (hyperalgesia) and nonpainful stimuli (allodynia) cause sustained activation of second-order neurons. NMDA receptor activation is linked to windup and central sensitization (i.e., decreased thresholds for response or increased vigor of responses after a sensitizing event) and may contribute to the maintenance of chronic pain conditions with processes occurring both at the dorsal horn level and in the supraspinal areas. Central sensitization may occur with all types of pain when prolonged primary afferent activation causes plasticity (adaptation) of the pain sensory thresholds in the CNS.[11]

One of the predominant contributors to pain propagation at the synapse and within the CNS is the glial cell. In the periphery, these are Schwann cells and satellite cells. In the CNS, these include oligodendrocytes, astrocytes, ependymal cells, and microglia. Glial cells account for 70% of the CNS and under normal conditions microglia account for 5% to 20% of glia.[12] The glial cells have historically been seen as support cells for synaptic homeostasis. This is true; however, they also have an important role in the synthesis, release, and uptake of neurotransmitters and serve as a link between the nervous system and the immune system. Nerve damage due to trauma, infection, drugs, or toxins exposes peripheral nerve proteins, and they are seen by the immune system as “nonself,” initiating an immune reaction. Glial cells are activated, causing release of cytokines and inflammatory mediators which contribute to peripheral sensitization, increasing nociceptor sensitivity, and lowering of the firing threshold. Continuous nociceptive input results in high levels of glutamate within synapses. In the setting of chronic pain, glial cells swell (called gliosis) and an increase in cell surface markers is seen. The more persistent the stimulus, the more they swell and release inflammatory mediators. This contributes to the development and maintenance of central sensitization.[13] Glial cells and NMDA receptors may also be activated by medications such as opioids. This is thought to contribute to opioid tolerance, dependence, addiction, and a phenomenon called opioid-induced hyperalgesia (OIH).[14]

Visceral pain is very complex. It follows somatosensory pathways and also its own systems. Aδ and C fibers have been found in the heart, pleura, abdominal cavity, gallbladder, and testicles. Additionally, the intestinal tract has its own neuronal system called the “brain–gut axis” that operates independently and in conjunction with the rest of the CNS.[15] Like the somatosensory pathways, peripheral and central sensitization occurs with chronic visceral pain. Activation of the autonomic nervous system may also affect visceral sensitivity and the role of emotions in modulating visceral pain. Visceral pain may be referred to areas of the somatosensory system (e.g., myocardial ischemia causes left arm pain), leading to a complex presentation of an individual's pain.[15,16]

SUPRASPINAL MODULATION AND THE DESCENDING PATHWAY

Once nociceptive signals reach the CNS (typically at the spinal cord level), they ascend to the thalamus, primarily via the spinothalamic tract. From the thalamus, tertiary neurons project to many structures in the brain, including the brainstem, diencephalon (includes the thalamus), primary and secondary somatosensory cortices, and frontolimbic area. The somatosensory cortex is where the brain interprets the qualities of pain such as location, duration, and intensity. Tertiary neurons also project to the limbic system, which is involved in the affective or emotional component of pain. Perception is when the sensory (physical) and affective (psychological) components of the nociceptive message are integrated into the patient's overall experience. An individual does not experience pain until the brain has processed and interpreted the electrical nociceptive signal.

A second tract, called the spinoreticular tract, ascends to the thalamus, but also branches off at the brainstem to stimulate descending modulation. Modulation happens throughout the CNS and results in either an increase or a decrease in transmission. Neurons from the thalamus and brainstem release inhibitory neurotransmitters, such as norepinephrine (NE), serotonin (5-HT), γ-aminobutyric acid (GABA), glycine, endorphins, and enkephalins, which inhibit EAA activity in the ascending pathway. GABA is more active at supraspinal sites, and glycine is more active at spinal sites. The GABA-A receptor is a binding site for benzodiazepines and barbiturates, and the GABA-B receptor is a binding site for baclofen, causing muscle relaxation. Glycine has both pronociceptive and antinociceptive effects, depending on the receptor. Endogenous opioids (endorphins, enkephalins) are the most common group of inhibitory peptides, inhibiting EAA release from the presynaptic terminals and activation of second-order neurons in the postsynaptic terminals. Opioids also enhance the descending pathway via release of NE and 5-HT. In fact, activation of most of the supraspinal structures results in enhancement of NE and 5-HT effects.

Diagnosis and Clinical Presentation

Pain is a symptom and a reactionary response to real or potential bodily harm, but it is not currently defined as a specific disease state. It also cannot be measured objectively. It is a symptom that relies on a patient's subjective report and any physical findings indicative of underlying pathology. Healthcare teams take on the task of identifying the cause of the pain using everything from noninvasive imaging such as magnetic resonance imaging to invasive testing such as electromyelograms and spinal discography.

Pain can be classified in many ways. Some conditions are classified as syndromes because the patient presents with a constellation of symptoms that cannot be attributed to any definitive diagnosis or disease process (e.g., complex regional pain syndrome). Often clinicians simply state the location and type of pain (e.g., neuropathic pain in bilateral lower extremities). Cancer-related pain, whether from the disease process itself or the treatment of the disease (e.g., surgery, chemotherapy, or radiation), presents very much like noncancer pain. One of the most common ways to classify pain is to describe the time course. Acute pain is caused by an injury or illness. It alerts an individual to the injury and initiates withdrawal from the noxious stimulus. It typically has an easily identified cause and location. The course is predictable, and the pain is expected to diminish in hours, days, or weeks as the injury heals. It may be associated with an inflammatory response, producing redness and swelling. Inadequately treated acute pain can evoke physiologic hormonal responses that alter circulation and tissue metabolism; these can also produce tachypnea, tachycardia, widening of the pulse pressure, and increased sympathetic nervous system activity. It can also cause emotional distress.

Chronic pain serves no biologic purpose. It is characterized by persistent pain that lasts beyond the length of an illness or the healing of an injury. Sometimes there is no apparent cause. It may be either continuous or recurrent and of sufficient duration and intensity to adversely affect a patient’s well-being, level of function, and quality of life. Risk factors for developing chronic pain include individual predisposition (e.g., female sex, increasing age, or a genetic predisposition), environmental factors (e.g., previous painful experiences or abuse), and psychological factors (e.g., anxiety, depression, or catastrophizing).[16]

Chronic pain can be further classified based on mechanism, symptoms, or location of injury. Musculoskeletal or inflammatory pain is described as constant, aching pain, often mediated by prostaglandins. It is usually caused by injury to the skeletal muscles or joints. Pain may be localized to the joints (as in rheumatoid arthritis and osteoarthritis) or more regional (as with myofascial pain or muscle strain). Neuropathic pain is described as tingling, sharp, shooting, stabbing, burning, or other uncomfortable feelings (dysesthesias) such as the sensation that there are bugs crawling on the skin. Neuropathic pain may be constant (as in diabetic peripheral neuropathy) or intermittent (as in trigeminal neuralgia). It is typically caused by injury within the nervous system or a nervous system response to persistent pain stimulus from outside the nervous system. Visceral pain can have a vague presentation, because the enteric and autonomic nervous systems are involved. Patients may report nausea or generalized abdominal discomfort (as in endometriosis, hepatitis, or pancreatitis). Some people report pain in the absence of physiologic tissue damage; however, their perception of the pain is very real. This is called dysfunctional pain. Conditions such as irritable bowel syndrome, fibromyalgia, interstitial cystitis, and some abdominal or pelvic pain fall into this category. In these conditions, pain appears to be generated by an imbalance in pronociceptive signals and antinociceptive signals in the CNS. Patients with dysfunctional pain syndromes are heavily influenced by factors that augment or diminish the CNS pathways (including stress, anxiety, depression, or illness).

Assessment

Pain is very subjective and difficult to measure in quantitative terms. It is essential to obtain a thorough history and examination, both physical and psychological. When obtaining a pain history, clinicians should gather details about the pattern, duration, location, and character of the pain and should additionally determine what makes the pain worse and what makes it better, what medications and nonpharmacologic therapies have been tried in the past, and the result of those therapies (positive or negative outcome) (Table 55-1).

Pain intensity should be measured using an appropriate pain scale according to the patient's ability to communicate (Table 55-2, Fig. 55-4).[17] Single-dimensional pain scales tend to be more accurate in the acute pain setting and not as helpful for chronic pain because they only capture a "snapshot" of what the patient is feeling. Chronic pain symptoms wax and wane over time, so more useful tools are multidimensional pain scales that evaluate function, including sleep, appetite, performance of activities of daily living, work, and social interactions. Examples of multidimensional tools include the McGill Pain Questionnaire and the Brief Pain Inventory.[18,19] Ultimately, the most useful aspect of patient assessment is the information provided by the patient on how pain impacts day-to-day life, such as the number of hours they spend on their hobbies, or how well they can perform activities of daily living. Some of the most difficult patients to assess are young children and patients with cognitive, visual, or hearing impairment. These patients may have difficulty describing and communicating their pain and discomfort. There are multiple assessment tools that are designed and tested in these special populations to increase the accuracy of pain assessment. In addition to physical and functional assessments, psychological evaluations help to identify those patients who may need more psychiatric or psychological therapy to help them cope with their chronic pain. Because controlled substances are used to treat chronic pain, some clinicians advocate for substance abuse screening (see Case 55-7, Question 4).

Overview of Treatment

Treatment of pain is based on guidelines whenever possible. However, the number of treatment guidelines for pain management is limited. More commonly, clinicians choose a therapy based on the type of pain (e.g., neuropathic, musculoskeletal, visceral, and central). For all types of pain, multimodal therapy including pharmacologic, physical rehabilitation, and cognitive behavioral therapy should be combined. Interventional therapies should be considered if possible.

A treatment plan must always include evaluation of the following factors: age, comorbidities (such as renal and liver disease), route of administration (the oral route may not be suitable), concurrent medications (for duplication or drug–drug interactions), laboratory abnormalities, and financial resources.

Acute pain is usually managed very effectively with nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen, and/or opioids, but may include adjunctive therapies as well. Pharmacotherapy for chronic pain is more complex. First-line agents for the treatment of neuropathic pain consist of antidepressants, preferably serotonin and norepinephrine reuptake inhibitors (SNRIs), including tricyclic antidepressants (TCAs). These agents enhance the descending inhibitory pain pathway. Anticonvulsants (e.g., sodium-channel blockers, calcium-channel blockers, or GABA agonists) are also considered first-line therapy for many common types of neuropathic pain. They inhibit activation of sodium and calcium channels, block release of EAAs such as glutamate, or block the postsynaptic receptors. Some anticonvulsants also enhance the inhibitory effects of GABA. If the pain is localized, topical agents may be useful (e.g., capsaicin or local anesthetics). Addition of an opioid may be considered if the former agents fail to provide adequate analgesia. Combination therapy has been shown to be more effective in some cases (TCA–anticonvulsant or opioid–anticonvulsant combinations).[20] Nerve blocks and other interventional therapies may be helpful for short-term relief.[21]

Chronic musculoskeletal pain usually responds to acetaminophen, salicylates, or NSAIDs, in addition to nonpharmacologic therapies such as heat and ice or physical rehabilitation modalities. Localized pain may be amenable to topical therapies (NSAIDs, capsaicin), and trigger points (i.e., taut muscle bands) may be amenable to injections. SNRIs may also be considered for this indication.[22,23]

Visceral pain is complex, and there are no clear treatment guidelines. Because it travels the somatosensory pathways, antidepressants that enhance inhibitory modulation are most commonly used. Additionally, anticonvulsants that reduce central sensitization and hyperalgesia may be helpful.[24]

Trials of any pharmacologic therapy must be monitored for both efficacy and toxicity. Patients must have realistic expectations for any medication trial. Even the most effective analgesics are expected to achieve only about 30% to 50% improvement in chronic pain. This is why multimodal therapy is essential. NSAID therapy should be accompanied by monitoring for dyspepsia, peptic ulcers, and gastrointestinal (GI) bleeding, elevated blood pressure, and declining renal function, at a minimum. Antidepressants do not usually require laboratory monitoring but are known to cause dry mouth, constipation, urinary retention, and drowsiness. Some of the anticonvulsants require laboratory monitoring for liver toxicity, electrolyte imbalance, or bone marrow abnormalities. All anticonvulsants may cause drowsiness, dizziness, and cognitive dysfunction, with short-term memory loss and word-finding difficulty. Opioids require laboratory monitoring for long-term adverse effects such as osteoporosis, hypogonadism, and end-organ impairment, and patients must be routinely screened for sleep apnea, constipation, drowsiness, nausea, and vomiting. Drug interactions, both pharmacokinetic (e.g., hepatic enzyme interactions) and pharmacodynamic (e.g., additive sedation), are common with many of these agents, particularly when used in combination.

Table 55-2

Pain Assessment Tools for Adults[17]

Tool	Method of Administration	Advantages	Disadvantages

Visual analog scale (VAS)	Verbal, visual	Reliable; sensitive to acute changes in pain	Requires paper/pencil, mechanical skills; decreased reliability with cognitive, visual or auditory impairment; not sensitive to long-term changes in pain
Numerical rating scales (NRS)	Verbal, visual	Reliable; good validity; detects treatment effects acutely	Decreased reliability with extremes of age; requires abstract thought, difficult to use with cognitive, visual, or auditory impairment; not sensitive to long-term changes in pain
Verbal description scales (VDS)	Verbal, visual (4- or 5-point scales)	Reliable; good validity; preferred by older adults; preferred by some over NRS or VAS	Dependent on literacy and language; limited number of response categories, unequal intervals between anchors; not very sensitive to changes in pain
Faces pain scale (FPS)	Visual	Reliable; good validity; good with poor literacy or language barrier; possibly easier than NRS or VDS	Requires abstract thinking; not specific for pain
Brief pain inventory (BPI)	Verbal, written	Reliable; intensity and interference components; sensitive to change in condition over time	Does not assess quality of pain or affective component
McGill Pain Questionnaire (MPQ)	Verbal, written (long form—30 minutes; short form—2–3 minutes)	Reliable; measures sensory and affective components; valid in older patients	Not recommended for illiterate or cognitively impaired patients

Perioperative Pain Management

It is estimated that 25 million inpatient surgeries and 35 million ambulatory surgeries are performed annually in the United States.[25] Greater than 80% of surgical patients experience postoperative pain and of those patients, up to 40% experience "severe" pain.[2] The mismanagement of postoperative pain, whether undertreatment or overtreatment, is associated with negative physiologic consequences such as persistent postoperative pain, impaired rehabilitation, increased hospital length of stay, and adverse events related to excessive analgesic use, including hospital re-admission. Multimodal treatment must be utilized throughout the perioperative continuum to effectively manage pain.

Pain management during the perioperative period can be divided into three phases: pre-, intra-, and postoperative analgesia. Preoperative analgesia is treatment started 1 to 2 hours before surgery, with medications used to decrease peripheral sensitization. Intraoperative analgesia prevents the establishment of central sensitization caused by incisional injury and includes only the intraoperative time period. Postoperative analgesia is aimed at proactively reducing acute pain and preventing central sensitization, thereby avoiding subsequent development of chronic pain.[26]

Table 55-3

Prevalence of Chronic Postsurgical Pain[28]

Type of Surgery	Incidence of Chronic Pain (%)	Clinical Presentation
Limb amputation	30–85	Phantom limb pain
Mastectomy	>50	Scar pain, phantom breast pain, shoulder or arm pain, chest wall pain
Thoracotomy	30–50	Scar pain, chest wall pain
Coronary artery bypass surgery	30–55	Sternal pain, postsaphenectomy pain
Inguinal hernia repair	20–60	Scar pain, ilioinguinal nerve pain, inflammatory pain

Source: Cregg R et al. Persistent postsurgical pain. Curr Opin Support Palliat Care. 2013;7:144–152.

Normally, the acute pain trajectory has a rapid decline during the first week after surgery, and most patients fully recover within a few weeks with no residual pain. Although there is no single definition of a time frame for chronic pain, chronic persistent surgical pain (CPSP) is usually regarded as pain of at least 2 months duration and which all other causes have been excluded.[27] The prevalence of CPSP is highest with limb amputation, thoracotomy, mastectomy, hernia repair, and cardiac surgery (Table 55-3).[28] Risk factors for CPSP include history of chronic pain prior to surgery, gender, age, surgical site, invasiveness of surgery, unrelieved postoperative pain, and comorbid anxiety or depression.[29] Genetic factors also account for a significant degree of inter-individual variation in pain sensitivity and treatment response.

CASE 55-1

QUESTION 1: B.B. is a 46-year-old female who sustained a shoulder injury while pulling a cart at work. She will be undergoing shoulder arthroplasty in 2 weeks. She also has fibromyalgia and takes hydrocodone/acetaminophen 5/325 mg 1 to 2 tablets by mouth every 6 hours (usually takes eight tablets daily) as well as duloxetine 30 mg by mouth daily and pregabalin 75 mg by mouth twice daily. She smokes one pack of cigarettes daily and has "a few" glasses of wine nightly to help her pain because she does not think her current analgesic regimen is effective.

What assessment should be done with B.B. prior to surgery? What risk factors does she have for increased pain after surgery?

It is paramount that all patients have a thorough preoperative assessment including review of medical comorbidities, medications, history of chronic pain, and substance abuse, as well as prior postoperative analgesic regimens and responses.[30] This might include evaluating kidney or liver function, pulmonary function, or coagulation status. Pharmacists should also ask about sleep apnea. The presence of central or obstructive sleep apnea is associated with a higher risk for perioperative complications including opioid-induced respiratory depression.[31] If the patient does not have a sleep apnea diagnosis, a screening tool called the STOP-BANG questionnaire can be utilized to assess the risk (Table 55-4).[32] The results of this screening are associated with postoperative critical care admission.[33] As part of a medication review, the pharmacist should consult with the respective state prescription drug monitoring program to determine what controlled substances the patient has been filling. It is expected that patients have only one prescriber of controlled substances so it is helpful to determine whether stated use matches the prescription history. Keeping with The Joint Commission standards, the pharmacist should reconcile outpatient medication profiles, contacting dispensing pharmacies if necessary.[34] Current and past substance use should be addressed in an open and nonjudgmental manner. Some hospitals perform urine drug testing to confirm prescription and/or illicit drug use.

Table 55-4

STOP-BANG Questionnaire[32]

Do you snore loudly?
Do you feel tired, fatigued, sleepy during the day?
Has anyone observed you stop breathing during sleep?
Are you being treated for high blood pressure?
BMI >35 kg/m^2
Age >50 years
Neck circumference >40 cm
Male gender
Yes to 3 or more item = high risk for OSA
Yes to <3 items = low risk of OSA

Patients always bring their past experiences and current fears to surgery. These factors affect how they perceive and cope with acute pain after surgery (Table 55-5). Risk factors for increased pain after surgery in B.B. include female gender, work injury, and chronic opioid therapy. Functional pain syndromes such as fibromyalgia are associated with inefficient diffuse noxious inhibitory control (DNIC). This means that the inhibitory pathway is not effectively blocking pain transmission into the CNS, and she will likely have an exaggerated pain response to surgery. Her chronic opioid use could also complicate pain management because she will likely require higher opioid doses after surgery.

CASE 55-1, QUESTION 2: What should be done to help B.B. prepare for surgery?

Clinicians should provide the patient and family with individually tailored education, including information on treatment options for management of postoperative pain, making sure to document the plan and goals in the medical record and on paper for the patient to take home.[30] Patient-tailored education has been shown to reduce postoperative opioid consumption, reduce preoperative anxiety, reduce requests for sedatives, and reduce length of stay.[30,35] Education should include changes in analgesics prior to surgery, reporting and assessment of pain and when to report, multimodal pharmacologic and nonpharmacologic options, as well as realistic goals for pain control.[7]

Table 55-5

Risk Factors for Increased Postoperative Pain[29]

Adverse experience with previous surgery
Preexisting pain (moderate–severe >1 month)
Psychological vulnerability
Younger age
Female

Workman’s compensation
Inefficient diffuse noxious inhibitory control (DNIC)
Genetic predisposition
Use of chronic opioid therapy

For B.B., there needs to be education about her substance use. Many surgeons require patients to stop smoking prior to surgery to improve healing (see Chapter 91 Tobacco Use and Dependence for smoking cessation strategies). Given her regular intake of alcohol, tapering off this prior to surgery is important, because she may develop alcohol withdrawal after surgery if she continues to consume alcohol. This complicates postoperative care and prevents use of valuable analgesics such as acetaminophen due to additive liver toxicity. Because she is getting little to no benefit from her opioid, it is recommended to discontinue hydrocodone/acetaminophen via taper over the next two weeks to reduce her tolerance and improve her postoperative response to opioid analgesics. Some time needs to be devoted to reducing her anxiety and educating her that she may have an exaggerated pain response. Increasing the dose of pregabalin may help with this as part of a multimodal analgesic regimen, and duloxetine could be continued.

CASE 55-1, QUESTION 3: Based on current guidelines, what postoperative pain management approaches are appropriate for B.B.?

Clinicians should use regional or intraspinal analgesia whenever possible to reduce the neuronal response to surgery. Surgery in the extremities is most often managed with regional nerve blocks, using a local anesthetic such as bupivacaine or ropivacaine. There are both sensory nerves and motor nerves that extend from the spinal cord. The sensory nerves carry pain, temperature, pressure, and chemical messages from the area of injury to the spine and brain for processing. Sensory nerves are small and very sensitive to local anesthetics. Local anesthetics act as sodium-channel blockers and, depending on how concentrated the local anesthetic is (0.05% vs. 0.1%), it is possible to achieve a very dense block and completely stop transmission. Unfortunately, with a really dense block, nerve transmission is retarded or stopped in the larger motor nerves as well, causing loss of motor function. For BB, the anesthesia team will consider a nerve block (likely an interscalene nerve block) either as a one-shot block or a continuous infusion. The one-shot blocks only last a few hours (Table 55-6). Because shoulder surgery is so painful and recovery so long, some hospitals send patients home with a continuous infusion of local anesthetic for pain relief up to 7 days. If they do this for B.B, she will have her arm in a sling because her arm and hand will be numb and not functional while the nerve block is running. This form of longer term acute analgesia has been shown to reduce length of stay as well as provide excellent pain relief.[36] Some surgeons use local anesthetics for localized joint or tissue infiltration in and around the surgical incision to offer short-term analgesia. A liposomal bupivacaine may be used as well. This may offer slightly longer analgesia in the area where administered.

For thoracic and abdominal surgeries, there are several analgesic options to reduce opioid need. Spinals are one-time injections of either opioid and/or local anesthetic into the subarachnoid (intrathecal) space. Because this is not a continuous infusion, the analgesia will wear off according to the half-life of the drug used. Some anesthesiologists use a small amount of epinephrine to cause local vasoconstriction and keep the medication from dispersing through the cerebrospinal fluid (CSF). Common complications with spinal injections include postdural puncture headaches (i.e., CSF can leak after puncture of the subarachnoid dura) and itching (with opioids). More serious complications include delayed respiratory depression (with opioids), hypotension (with local anesthetics), infection, and intraspinal hematomas.

Epidurals offer the convenience of a continuous infusion of opioid and/or local anesthetic. The medication chosen, concentration, and infusion rate all offer different options for a given clinical situation. Morphine, hydromorphone, and an agent from the fentanyl family are the opioids most commonly used. The pKa and lipophilicity help determine the best agent. Morphine and hydromorphone are more hydrophilic so it is more difficult for them to pass through membranes (to get into the CSF or systemic blood) once injected into the epidural space. This is advantageous because they stay in that space, and infusions can be used for up to 7 days. The fentanyl-related agents are highly lipophilic and easily pass through membranes into the systemic circulation and CSF. Typically, they are not used for longer than 24 hours due to this, but are often used for epidurals during labor. All epidural opioids travel cephalad to the brain via the CSF and may cause central respiratory depression. Epidural opioids also cause typical class-related adverse effects such as itching and nausea, and cognitive effects such as sedation or confusion, although these are centrally mediated.

Some clinicians limit opioid use further by only using local anesthetics in epidural infusions. The local anesthetic chosen depends on half-life and toxicity. Lidocaine is used for local infiltration because it has a short onset of action. However, it also has a short half-life so usually bupivacaine or ropivacaine is used for blocks (Table 55-6). Usually these are infused via an epidural catheter. The catheter tip is placed where the densest block is needed. The greater the concentration, the denser the block. Increasing the infusion rate causes the local anesthetic to spread over more spinal nerve roots. This causes a greater clinical area of anesthesia. For example, if a patient has a total colectomy and the incision area is still painful on the most cephalad part, the infusion rate can be increased so some of the higher nerve roots are covered. Local anesthetics must be monitored not only for pain coverage but also for toxicity. They most commonly cause hypotension, because sympathetic nerves are small. The more cephalad the epidural catheter tip is placed, the more likely that the sympathetic nerves serving the lungs, diaphragm, and heart will be affected. Local anesthetic systemic toxicity (LAST) can be life threatening, causing seizures and cardiac dysrhythmias. The treatment of LAST involves rapid administration of intralipid, which will bind the local anesthetic.[37]

Table 55-6

Local Anesthetics

Agent	Onset (minute)	pKa	Duration (hour)	Maximum dose (mg/kg)
Lidocaine	10–20	7.8	1–2	4.5
Mepivacaine	10–20	7.7	1.5–3	5
Prilocaine (topical)	<60	8.0	1–2	6
Ropivacaine	15–30	8.1	4–8	2.5
Bupivacaine	15–30	8.1	4–8	2.5
Chloroprocaine	10–15	9.1	0.5–1	9
Procaine	2–5	8.9	0.75–1	7
Tetracaine	3–5	8.4	3	1.5
Cocaine (topical)	1	8.7	0.5	0.5

Multimodal Pain Management

CASE 55-2

QUESTION 1: D.K. is a 35-year-old male admitted for elective surgery of an inguinal hernia that has been present for 8 months. The hernia presented as a protruding bulge, 4 cm in diameter, in the lower right abdominal quadrant that was noticeable with standing and retracted inward when lying down. There was no pain initially with the hernia or incarceration of internal structures so conservative management with observation was appropriate until approximately 4 weeks ago when the patient noted the size of the hernia was increasing and experienced pain shooting down the right leg when walking. An ultrasound of the right groin confirmed an inguinal hernia sac, 6 cm in diameter, with no incarceration. The patient was scheduled for an open repair using the Lichtenstein technique with polypropylene mesh reinforcement of the anterior abdominal wall. Prior to admission for the surgery, the patient's medical history included:

Medical conditions:
  Morbid obesity (height 1.8 m, weight 171 kg, BMI 51.5 kg/m^2)
  Type 2 diabetes, noninsulin dependent
  Sleep apnea, uses CPAP at home
  Chronic kidney disease, baseline serum creatinine 1.4 mg/dL
  Hypertension
Medications:
  Glimepiride 8 mg orally once daily
  Lisinopril 20 mg orally once daily
  Ibuprofen 600 mg orally once or twice daily for groin pain

In the postoperative anesthesia care unit (PACU), morphine 2 to 4 mg intravenous every 5 minutes is ordered for severe pain. D.K. received 8 mg of intravenous morphine over 30 minutes then became very drowsy but still reporting severe pain. The nurse is concerned about the level of sedation and does not want to give additional morphine. Is morphine an appropriate opioid for postoperative pain control in D.K.?

After surgery is completed in the operating room, patients are transferred to the PACU for stabilization of respiratory function and pain. Most patients emerging from general anesthesia are still quite sedated when they are transferred to the PACU. When the anesthetic agents begin to wear off, it is very important to achieve rapid control of severe pain so frequent administration of small intravenous opioid doses is common practice in this setting. Currently, there is not a universally accepted standard for titration of intravenous opioids in the PACU. Some institutions will allow use of both intravenous fentanyl to gain fast pain control and morphine for a longer duration of action. Hydromorphone is an acceptable alternative to morphine for patients with renal insufficiency or intolerable side effects to morphine.

Morphine is considered the standard for intravenous opioid administration. The hydrophilic (i.e., water soluble) property of morphine delays penetration across the blood–brain barrier so the relative time to onset is approximately 6 minutes after an intravenous dose. The concentration peak effect (i.e., equilibration time between the plasma and brain) after an intravenous morphine dose is 20 minutes.[38] Major morphine metabolites include morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G).[39] The M3G metabolite is inactive but M6G crosses the blood–brain barrier and has potent analgesic activity. Therefore, the analgesic and ventilatory depressant effects of morphine and M6G may not be evident with initial high plasma morphine concentrations.[40] Adverse events may occur 40 to 60 minutes after the last intravenous morphine dose.[40] Patients with renal insufficiency will have M6G metabolite accumulation and be at increased risk for respiratory depression so morphine use is not recommended in this population.[41]

Hydromorphone is commonly used in patients who cannot tolerate morphine or have a history of renal insufficiency.[42,43] Hydromorphone is a hydrogenated ketone analogue of morphine with slightly higher lipid solubility. The concentration peak effect after intravenous hydromorphone administration is between 8 and 20 minutes.[44,45] Hydromorphone has a similar metabolic pathway to morphine producing hydromorphone-3-glucuronide (H3G) and hydromorphone-6-glucuronide (H6G). However, hydromorphone metabolites are devoid of analgesic activity but H3G has been showed to accumulate in animal models leading to dose-dependent myoclonus.[45]

Fentanyl is a synthetic phenylpiperidine compound with high lipid solubility resulting in rapid transfer across the blood–brain barrier. The concentration peak effect after intravenous fentanyl administration can be seen within 4 to 6 minutes.[46] Fentanyl is a good option for rapid pain control but may accumulate in adipose tissue with multiple doses; therefore, it is not the best choice for obese patients.[46]

For management of D.K.'s pain in the PACU, the morphine order should be changed to intravenous hydromorphone at 0.2 to 0.4 mg every 10 minutes for severe pain. Hydromorphone does not have appreciable metabolite accumulation with renal insufficiency and does not distribute into adipose tissue. After D.K.'s pain is stabilized in the PACU, the interval will need to be longer between doses due to the declining acute pain trajectory and addition of other multimodal medications that will decrease the opioid requirements (Table 55-7). In addition to pain management, it is very important to anticipate postoperative nausea and vomiting (PONV) caused by anesthetic agents and opioids. Antiemetics are commonly used for prevention of severe PONV (refer to Chapter 22 for management of PONV).

CASE 55-2, QUESTION 2: Is D.K. an appropriate candidate for intravenous patient-controlled analgesia (PCA)?

For postoperative pain management after discharge from the PACU, the oral route is preferred over intravenous administration unless the patient is unable to use this route or has severe uncontrolled pain.[30] The use of PCA provides a precise and convenient method for intravenous opioid administration that allows the patient to activate the dose for acute pain management. The intravenous PCA route is preferred over nurse-administered intravenous doses because the patient does not have to notify the nurse when more medication is needed, wait until it is given, and then further wait for the peak effect to occur for pain relief. Self-administration of smaller and more frequent intravenous opioid doses reduces the variation between the peak and trough effect of the dosing interval thus better maintenance of the plasma opioid concentration.[47] Evidence-based guidelines on the management of postoperative pain strongly recommend use of PCA for the intravenous route in surgical patients because of ileus, aspiration risk, or inability to take medications orally or enterally.[30]

Table 55-7

Postoperative Transition of Opioid Doses for Naive Patients >50 Kg[30,42,48]

Postanesthesia Care Unit
Fentanyl intravenous 25–50 mcg every 5 minutes as needed Morphine intravenous 2–4 mg every 5 minutes as needed Hydromorphone intravenous 0.2–0.4 mg every 5 minutes as needed
Medical/Surgical Hospital Floor
Patient-controlled Analgesia (PCA) Starting Dose
Morphine intravenous 1 mg every 10 minutes Hydromorphone intravenous 0.2 mg every 10 minutes Fentanyl intravenous 25 mcg every 10 minutes
Nurse-Administered Opioid Dose for Patients Unable to Use PCA
Morphine intravenous 2–4 mg every 2 hours as needed

Hydromorphone intravenous 0.25–0.5 mg every 2 hours as needed
Discharge Planning
Hydromorphone 2–4 mg orally every 4 hours as needed Oxycodone 5–10 mg orally every 4 hours as needed (can be combined with acetaminophen 325 mg) Hydrocodone 5 mg with acetaminophen 325 mg—1 to 2 tablets orally every 4 hours as needed
Important
Long-acting opioid formulations are not recommended for acute postoperative pain management unless the patient was taking opioid therapy for chronic pain prior to surgery.

Patients who are appropriate for PCA must be able to cognitively understand how to use a dose button for opioid self-administration and require intravenous opioid for many hours.[30] The PCA dose button is connected to an infusion pump that will allow the administration of an opioid dose when the button is pushed (i.e., demand). To prevent over dosage by continual demand, all PCA devices use a lockout interval which is the length of time after a successful patient demand during which the device will not administer another dose even if the patient pushes the button.[47] Most patients who start intravenous PCA are opioid-naïve meaning that their opioid use the week prior to surgery was less than 60 mg of oral morphine or its equivalent.[42,48] For this reason, the starting dose for intravenous PCA is standardized for opioid-naïve patients (Table 55-7).

Use of a continuous opioid infusion for postoperative pain management is generally reserved for patients who are opioid-tolerant and were taking opioid medication around-the-clock prior to surgery. The role of the continuous infusion is to provide a steady baseline of opioid medication that mimics the dose taken prior to surgery. Equianalgesic dose calculations are used to determine the dose difference between two opioids to provide the same degree of pain relief. When switching between two opioids, it is recommended to decrease the new calculated dose by 25% to 50% to account for incomplete cross tolerance that may occur.[42] Use of intravenous PCA along with a continuous infusion in opioid-tolerant patients can help fine-tune pain control (refer to Case 55-8 for examples of equianalgesic dose calculations).

Respiratory depression remains the most serious adverse event related to opioid therapy often due to excessive amounts or frequent use of opioid medication beyond what is needed to achieve pain control.[42,47] There are many factors that increase the risk of opioid-induced respiratory depression with intravenous PCA related to comorbid medical conditions. Patients with advanced age >65 years, renal insufficiency, history of sleep apnea, or morbid obesity are at higher risk for developing opioid-induced respiratory depression. To prevent respiratory depression in high-risk patients, the lowest possible starting dose of an opioid should be initiated, and use of a continuous infusion should be avoided. For all patients, avoid administration of more than one drug with sedating properties at the same time with opioids.[30] Medications including antihistamines, benzodiazepines, gabapentin, pregabalin, and skeletal muscle relaxants should be scheduled approximately 2 hours apart to prevent accumulation of sedating side effects.

For hospitalized patients who experience excessive sedation and cannot be aroused with sternal stimulation, or have a significant decline in breathing, naloxone administration may be needed to reverse the opioid CNS effects. Naloxone is a nonselective competitive opioid antagonist of all pharmacologic effects on mu, delta, and kappa receptors. After oral administration, naloxone is extensively metabolized in the liver (i.e., >95% first pass effect) and not effective so intravenous, intramuscular, or subcutaneous administration at a dose of 0.4 mg is required for reversal of life-threatening respiratory depression. The extent and duration of naloxone reversal of opioid-induced respiratory effects is highly variable and is related to many factors, including the specific opioid used, the opioid dose, administration mode, concurrent medication, underlying disease, and pain. Therefore, naloxone administration may need to be repeated every 2 to 3 minutes or given as a continuous infusion until full recovery of respiratory function.[49]

In this case, PCA therapy would be appropriate for D.K. based on the invasive surgery and anticipated severe postoperative pain. Hydromorphone 0.2 mg intravenously with a lockout interval of 10 minutes is recommended because D.K. is at high risk for respiratory depression being opioid-naïve, morbidly obese, and having chronic renal insufficiency. Because D.K. is experiencing sedation due to morphine administration in the PACU, the PCA dose should be started after he is more alert. Other analgesic medications that are not sedating should be used to provide synergistic pain management and can be used throughout the postoperative period.

As soon as DK can tolerate oral medication, the intravenous PCA dose should be discontinued and a short-acting oral opioid such as oxycodone or hydromorphone administered as needed with frequent reassessment of pain. Because DK is opioid-naïve, the lowest starting dose should be prescribed so oxycodone 5 to 10 mg every 4 hours as needed or hydromorphone 2 to 4 mg every 4 hours as needed would be options in this case. Oral short-acting morphine is not recommended due to concern for metabolite accumulation with renal insufficiency. Long-acting oral formulations (i.e., sustained or extended release) should be avoided in opioid-naive patients who cannot tolerate around-the-clock opioid administration for a prolonged period of time. Recent guidelines for postoperative pain do not recommend long-acting oral opioids due to the need for pain titration with short-acting opioid, and studies have not shown that pain control with a long-acting opioid is superior to short-acting opioid administration immediately after surgery.[30]

When DK is ready for discharge, a prescription for a limited supply of short-acting opioid should be written to cover the duration of 3 days.[50] This is particularly important because prescription opioid abuse is a national crisis and prescription opioid overdose is now the leading cause of unintentional deaths in the United

---

States.[50] It is estimated that 35% to 80% of people addicted to prescription opioids report that they were first exposed to opioids for the legitimate treatment of pain, including postsurgical pain.[6] The use of nonopioid medication can help reduce the need for opioid therapy.

CASE 55-2, QUESTION 3: What other nonopioid medications would be helpful in the management of D.K.'s postoperative pain?

Recent guidelines on postoperative pain management reviewed studies on acetaminophen and NSAIDs in conjunction with opioids and found that the combination of both medications is more effective than either drug alone in reducing pain and opioid consumption.[30] Perioperative oral acetaminophen at a dose of 1,000 mg 3 or 4 times/day for 48 hours after surgery in adults with normal liver function is supported in the literature.[51] After the initial postoperative period, the dose should be reduced to 650 mg and administered on an "as-needed" frequency. To reduce the risk of liver toxicity associated with acetaminophen daily totals exceeding 3,000 mg, patients who will need opioid therapy should not be prescribed combination products containing acetaminophen such as oxycodone/acetaminophen or hydrocodone/acetaminophen. Use of intravenous acetaminophen has generally been reserved for patients who cannot take oral medications after surgery and cannot use NSAIDs due to increased risk of gastrointestinal bleeding or renal insufficiency. Most research indicates that there is no clear difference between intravenous and oral acetaminophen in reducing postoperative pain.[30,52]

Compared with acetaminophen, NSAIDs are more efficacious for reducing postoperative pain due to their anti-inflammatory effects. Most of the oral nonselective NSAIDs are comparable in efficacy so selection may be influenced by other factors such as cost, availability for use over the counter, and lower cardiovascular adverse effects. All NSAIDs are contraindicated for management of perioperative pain in patients who undergo coronary artery bypass graft surgery because of an increased risk of cardiovascular events.[30] Refer to Chapter 43 Osteoarthritis for more detailed information on NSAIDs.

Intravenous ketorolac is a nonselective NSAID and very effective in reducing postoperative pain. The recommended ketorolac dose for adult patients <65 years with normal renal function is 30 mg every 6 hours as needed. For patients over 65 years of age or with mild-to-moderate renal failure, the dose of ketorolac must be reduced to 15 mg every 6 hours as needed. The maximum duration for ketorolac administration is limited to 5 days to prevent adverse events related to gastrointestinal bleeding with prolonged use. It is not recommended to administer ketorolac to patients who are hypovolemic postoperatively due to excessive blood loss or dehydration due to the risk for renal injury.[30]

Gabapentin or pregabalin are neuromodulators that are helpful in reducing postoperative neuropathic pain. The initial dose should be based on the patient's use prior to admission. For patients who were not taking gabapentin or pregabalin for chronic pain prior to surgery, the dose should be titrated up from the lowest dose and adjusted for renal function (Table 55-8). Patients who were taking gabapentin or pregabalin for preexisting neuropathic pain prior to surgery should have their dose and frequency resumed as soon as possible postoperatively to prevent uncontrolled chronic pain.

Table 55-8

Pharmacologic Options for Treatment of Neuropathic Pain

Drug	Dose[a]	Adverse Effects	Monitoring/Comments
Carbamazepine[b]	200 mg TID, titrate to max 400 mg TID	Diplopia, rash, hepatitis, neutropenia, aplastic anemia, dizziness, cognitive effects, hyponatremia	Check LFTs, CBC, sodium at baseline and every 3 months during therapy, periodic serum levels
Oxcarbazepine	75 mg BID, titrate to max 1,200 mg BID	Rash, cognitive effects, hyponatremia, sedation, blurred vision, nausea	Check sodium every 2 weeks for 3 months, then with dose increases
Lamotrigine	25 mg daily, titrate to max 200 mg BID	Desquamating rash, cognitive effects	Requires very slow titration to avoid rash
Topiramate[b]	25 mg BID, titrate to max 200 mg BID	Nausea, anorexia, paresthesias, metabolic acidosis, cognitive effects, nephrolithiasis	Check serum bicarbonate at baseline and every 3 months or with each dose increase
Lacosamide	50 mg BID, titrate to max 200 mg BID	Nausea, vomiting, dizziness, diplopia, ataxia, fatigue, rash, atrial fibrillation/flutter	ECG at baseline and with dose adjustments, especially in patients at risk for cardiac conduction abnormality Reduce dose for renal and liver impairment
Gabapentin[b]	300 mg daily, titrate to max 1,200 mg TID	Somnolence, dizziness, edema, cognitive effects	Reduce dose for renal impairment or elderly patients
Pregabalin[b]	75 mg BID, titrate to max 300 mg BID	Same as gabapentin	Same as gabapentin
Amitriptyline, Nortriptyline	10 mg QHS, titrate to 100 mg QHS	Dry mouth, constipation, urinary retention, orthostatic hypotension, somnolence	Caution in elderly patients
Duloxetine[b]	30 mg daily, titrate to max 60 mg daily	Nausea, dry mouth, headache, diarrhea, fatigue, sweating, anorexia	Contraindicated with liver disease or concurrent alcohol consumption

---

Venlafaxine	37.5 mg daily, titrate to max 225 mg daily	Headache, nausea, sweating, sedation, hypertension, seizures, tachycardia	Serotonergic effects <150 mg and noradrenergic effects >150 mg Monitor blood pressure and heart rate
Opioids[b]	10–15 mg morphine every 4 hours or equianalgesic dose of other opioid	Somnolence, respiratory depression, dry mouth, constipation, urinary retention	May cause confusion in elderly patients Use with a bowel regimen Monitor for misuse and abuse
Tramadol[b]	25 mg QID to max 100 mg QID	Somnolence, dry mouth, constipation, Seizures, Serotonin syndrome	Caution with antidepressants
Capsaicin cream[b]	Apply QID	Rash, burning feeling on skin	Avoid contact with mucous membranes, eyes
Capsaicin patch[b]	Apply 1 patch for 1 hour, every 3 months	Skin irritation at application site, burning feeling on skin	Must be applied in medical office
Lidocaine patch[b]	Apply 1–3 patches daily for 12 hours	Skin reaction at site of application	

[a] All oral agents are titrated up to reduce adverse effects and titrated down when discontinuing therapy.

[b] Food and Drug Administration–approved for treating pain conditions.

BID, 2 times a day; CBC, complete blood cell count; ECG, electrocardiogram; LFTs, liver function tests; QHS, every night at bedtime; QID, 4 times a day; TID, 3 times a day.

The use of ketamine is becoming increasingly popular postoperatively in patients with a history of chronic pain that is poorly responsive to traditional analgesic medications including opioids. Ketamine is a NMDA receptor antagonist that is effective in decreasing central sensitization after surgery. There is insufficient evidence in the literature on the optimal ketamine dose and duration of use postoperatively. Doses for postoperative intravenous ketamine bolus dosing or continuous infusion range from 0.1 to 0.5 mg/kg.[30] The main side effect of postoperative ketamine is hallucinations which can be mitigated by keeping the dose low. Ketamine is contraindicated in patients with uncontrolled hypertension.

Intravenous lidocaine has been evaluated as part of multimodal analgesia in patients who underwent open or laparoscopic abdominal procedures. Studies showed that perioperative or intraoperative intravenous lidocaine infusions were associated with shorter duration of ileus and better quality of analgesia compared to placebo.[30] In trials, lidocaine was typically administered as an intravenous bolus (100–150 mg or 1.5–2.0 mg/kg) followed by an infusion of 2 to 3 mg/kg/hour through the end of surgery.[53,54] Topical local anesthetics such as the lidocaine 5% patch may be helpful for incisional pain, but its efficacy is limited due to lack of penetration into deeper tissues.

D.K. should have acetaminophen started at 1,000 mg orally scheduled every 8 hours as soon as he is alert enough to swallow medication without risk of aspiration. NSAIDs should be avoided in the immediate postoperative period until his renal function can be evaluated. If D.K.'s creatinine clearance is >50 mL/minute, ibuprofen 600 mg orally every 6 hours as needed can be used for pain because this was the patient's NSAID choice. Prior to admission, D.K. was reporting pain shooting down the right leg but was not taking medication for neuropathic pain. If the shooting pain persists postoperatively, gabapentin started at a low dose of 100 mg orally scheduled 3 times a day may be helpful. Caution should be used with gabapentin in patients with renal insufficiency which may require a dose adjustment. Intravenous lidocaine is generally not a first-line option for postoperative pain management and should be used only if pain control is suboptimal after maximizing other multimodal medications. Before D.K. is discharged, plans should be made for prescribing the oral multimodal medications for a short duration of time because acute postoperative pain generally abates after one to 2 weeks.

LOW BACK PAIN

Low back pain occurs at a rate of 1.39/1,000 person-years in the United States, including 3.15% of all emergency visits. These are typically injuries occurring in the home.[55] It has been reported that low back pain affects 70% to 85% of adults at some point in their lives, and 12 months after the onset of low back pain, 45% to 75% of people still have pain.[56,57] There is a bimodal distribution with peaks between 25 and 29 years of age (2.58/1,000 person-years) and 95 to 99 years of age (1.47/1,000) without differentiation by underlying etiology.[56] There is an association between psychological factors and the occurrence of low back pain, including anxiety, depression, somatization symptoms, stress, and negative body image. Chronic low back pain patients have higher rates of emotional distress and depression (25%) relative to acute low back pain subjects (2.9%).[58] Socioeconomic risk factors include job dissatisfaction, physical work, psychologically stressful work, low educational achievement, and workers' compensation insurance.[59] Biomechanical and physical work factors such as heavy lifting, repetitive motion, non-neutral body postures, and vibration are established risks for back disorders.[60] Chronic low back pain also creates a large financial burden on the workplace. Low back pain accounts for almost $20 million in lost productivity annually, and patients who have been on disability for more than 1 year rarely return to work.[61]

Low back pain, by definition, affects the lumbosacral spine and associated muscles and nerves. It is multifactorial in nature, either nociceptive (musculoskeletal, myofascial), neuropathic (radicular pain), or has a central sensitization component.[62] In about 85% of cases, no pathophysiologic cause can be found.[63] The functional spinal unit is made up of two vertebral bodies, two zygapophyseal (facet) joints, the intervertebral disc, and the supporting ligamentous structures (Fig. 55-5). The facet joints of the spine form the junction where vertebral bodies meet. The joint space is maintained by cartilage and fluid in the joint. Like all weight-bearing joints of the body, the spine also develops joint space narrowing, bony hypertrophy, and deterioration of cartilage with normal use, resulting in the musculoskeletal pain of OA. If the spine is used more, as with jobs involving heavy lifting and manual labor, the joints deteriorate faster. In addition to deterioration of the facet joint spaces, the intervertebral discs lose water content with time and may become desiccated, reducing the cushion between the vertebral bodies. These discs are fragile and can be torn or damaged and may herniate into the spinal canal foramen (Fig. 55-5). If vertebral bodies shift because of deterioration, spondylolisthesis may occur. This shift, or a herniated disc, may impinge on the spinal nerve root, or cause nerve root irritation, which can produce radicular neuropathic pain. This is sometimes referred to as sciatica. Shifting of the vertebral bodies may also reduce the size of the foramen where the nerves exit the spinal cord (spinal stenosis). If the vertebral bodies shift too far into the central spinal canal, pressure can be exerted on the spinal cord, which may lead to spinal cord injury and subsequent loss of sensory and motor nerve function (paralysis). If the motor nerves are affected (as with lower extremity muscle weakness, bowel or bladder incontinence), a “red flag” is present and surgery may be necessary to preserve function. Table 55-9 lists other serious conditions that call for immediate medical or surgical attention.[64] Sometimes low back pain is more intense than would be expected, or is much more widespread than imaging would predict. These are hallmarks of central sensitization.[62]

Myofascial pain is very common in patients with chronic low back pain. Myofascial pain is localized to specific regions or muscle groups. It affects all age groups and is associated with numerous other pain conditions. It is classically associated with muscle knots called "trigger points." A trigger point is described as a hyperirritable spot in skeletal muscle that is associated with a palpable "taut band" of muscle. Trigger points are hypothesized to evolve from excessive acetylcholine release from the motor endplate, leading to sustained muscle fiber contracture. Development of trigger points is usually associated with mechanical overuse or overload of a muscle group (as with repetitive work). It is also associated with postural problems, prolonged static positions, emotional stress (causing muscles to tense), and nutritional deficiencies (such as vitamins B_1, B_6, B_{12}, and D, iron, magnesium, and zinc) or metabolic problems such as thyroid disease. It is thought that low-intensity exertions related to static posture cause small muscle fibers to be continuously activated, leading to the development of trigger points.[65] Nociceptors are abundant in muscle nerves, and there are a variety of nociceptors that can be stimulated by substances such as prostaglandins, bradykinin, protons, ATP, 5-HT, and glutamate, which are released from damaged tissue. The neuropeptides, substance P and CGRP, are also found in the nociceptor terminals, which stimulate the inflammatory cascade, leading to peripheral sensitization and the clinical manifestation of muscle pain. Continuous activation of muscle nociceptors leads to release of substance P and glutamate from the presynaptic terminal at the dorsal root ganglion. These substances activate postsynaptic AMPA and NMDA receptors, respectively, and subsequently may lead to neuroplasticity (Fig. 55-3).

Table 55-9

Red Flags for Potentially Serious Conditions that Cause Back Pain[64]

Possible Fracture	Possible Tumor or Infection	Possible Cauda Equina Syndrome
Major trauma, such as vehicle accident or fall from height	Age <20 or >50 years	Saddle anesthesia
Minor trauma or strenuous lifting in older or potentially osteoporotic patients	History of cancer	Recent onset of bladder dysfunction (e.g., urinary retention, increased frequency, overflow incontinence)
	Constitutional symptoms (recent fever, chills, unexplained weight loss)	Severe or progressive neurologic deficit in the lower extremities
	Risk factors for spinal infections: Recent bacterial infection IV drug abuse Immune suppression	Unexpected laxity of the anal sphincter
	Pain that worsens when supine	Perianal/perineal sensory loss
	Severe nighttime pain	Major motor weakness: Quadriceps (knee extension weakness) Ankle plantar flexors, evertors, and dorsiflexors (foot drop)

IV, intravenous.

Acetaminophen is considered the safest choice for the management of musculoskeletal pain. Its mechanism of action is not well defined, but it has analgesic activity in the CNS. It has no peripheral clinical effect on prostaglandins, so it lacks typical anti-inflammatory activity. Use of acetaminophen therefore avoids the GI, renal, and cardiovascular toxicities associated with NSAIDs. NSAIDs reduce pain and inflammation by inhibiting cyclooxygenases (COX-1 and COX-2) at the site of injury and along the ascending pain pathway. The NSAIDs are equally effective across the drug class, although some patients may respond to one agent better than another. They are more effective as monotherapy for acute low back pain than in combination with a muscle relaxant or an opioid. A meta-analysis showed that NSAIDs are better than placebo for back pain without neuropathic symptoms, but not for back pain with neuropathic symptoms.[66,67] COX-2 selective inhibitors are as effective as traditional NSAIDs for analgesia but are better tolerated.[67] Celecoxib is the only COX-2 selective inhibitor available in the United States. Acetaminophen may be used in combination with NSAIDs for additive analgesia.

There are several guidelines published for the management of low back pain. Koes et al. reviewed evidence-based management guidelines from 13 different countries and 2 international committees that were published between 2000 and 2008.[65] Table 55-10 presents a summary of common recommendations. All guidelines were in agreement with the use of simple analgesics such as over-the-counter acetaminophen and NSAIDs for first-line therapy for both acute and chronic low back pain. Both of these medication classes are considered effective for short-term use, although their effects are modest. Because the guidelines have been published, a meta-analysis of acetaminophen versus placebo for spinal pain and osteoarthritis found acetaminophen to be ineffective for long-term use in chronic pain.[68] This would make NSAIDs the ideal first-line analgesic, if there are no contraindications.

Most guidelines recommend either muscle relaxants or weak opioids as third-line choices for short-term use in either acute or chronic low back pain. Despite the fact that muscle relaxants are used commonly, there is no evidence that they are effective for chronic low back pain. Agents such as cyclobenzaprine and tizanidine, as well as benzodiazepines such as diazepam, show moderate efficacy in the short-term (<2 weeks) but are associated with a higher incidence of adverse effects than placebo.[69] Weak opioids such as tramadol have also shown modest relief with short-term use (<4 weeks).[70,71] There are several studies showing some efficacy for most long- and short-acting opioids, but they do not show any long-term functional improvement or return to work.[72–74]

A few guidelines, including those from the American Pain Society (APS), recommend use of antidepressants or anticonvulsants for neuropathic pain symptoms.[70] Antidepressants, specifically the TCAs, have shown modest analgesia compared with placebo, but they have not been shown to be effective for acute low back pain, nor have they shown demonstrable improvement in function.[67,68,75,76] Duloxetine, an SNRI, has shown efficacy and safety for the treatment of low back pain.[77] There have been a very small number of trials using the anticonvulsants topiramate and gabapentin for back pain. Anticonvulsants traditionally have been helpful for treating neuropathic pain (e.g., peripheral neuropathies) but produce only small improvements for back pain with radiculopathy.[78–80]

Table 55-10

Summary of Common Recommendations for Treatment of Low Back Pain[65]

Acute or Subacute Pain
Reassure patients that diagnosis is not serious

Advise to stay active
Prescribe medication if necessary
First line: acetaminophen
Second line: NSAIDs
Third line: muscle relaxants, opioids, antidepressants, or anticonvulsants as coanalgesics
Discourage bed rest
Do not recommend supervised exercise program
Chronic Pain
Discourage use of alternative therapies (ultrasound, electrotherapy)
Short-term use of medication/manipulation
Supervised exercise therapy
Cognitive behavioral therapy
Multidisciplinary treatment

NSAIDs, nonsteroidal anti-inflammatory drugs.

Myofascial pain treatment is aimed at correcting precipitating behaviors including ergonomic factors. Physical rehabilitation is essential for teaching patients appropriate stretching and strengthening exercises, as well as postural support and stabilization. Some clinicians inject the trigger point(s). There are several techniques that are all equally effective, including dry needling, saline injection, local anesthetic injection or botulinum toxin. Several other pharmacologic therapies may be used, but none have more than anecdotal support. General approaches to pain management, including NSAIDs, muscle relaxants, antidepressants, anticonvulsants, and opioids, may be helpful for individual patients. Vitamin D deficiency has been linked to chronic musculoskeletal pain, although this is somewhat controversial.[81,82]

CASE 55-3

QUESTION 1: J.P. is a 48-year-old man who presents with low back and leg pain. He has had chronic back pain for several years, which has progressively worsened during the last several months. He reports an aching pain that is localized to his lumbosacral spine with some radiation into his buttocks and hips. He also describes burning pain into his right leg all the way down to his toes. He rates his pain as 7 out of 10 on the numeric pain scale. On good days, his pain is 5 of 10. He recently did some yard work and had an acute exacerbation of his pain. He reports that this felt like 10 out of 10 on the numeric pain scale, and he was in bed for the following 2 days because of pain. He is usually able to do some chores around the house, but activity makes his pain worse. He sleeps poorly (only about 4–5 hours/night), and he does not go out or socialize very often because he is afraid this will exacerbate his pain. He used to golf and play softball but is not able to participate in these hobbies any more as a result of pain. He smokes two packs of cigarettes daily and drinks about a six-pack of beer each week. He was previously a plumber but had to quit his job earlier this year because of health problems. He denies any lower extremity weakness and also denies loss of bowel or bladder control. He has not found anything that really helps his pain except rest and acetaminophen/codeine that his sister gave him. His past medical history includes hypertension, hyperlipidemia, depression, and morbid obesity. His current medications are lisinopril for hypertension, simvastatin for hyperlipidemia, carisoprodol, cyclobenzaprine as needed, a baby aspirin, and acetaminophen/codeine. He also takes three tablets of over-the-counter strength (200 mg/tablet) ibuprofen and three tablets of extra strength (500 mg/tablet) acetaminophen about four times daily with minimal relief of his pain. Upon physical examination, J.P. has pain with palpation along his lumbar paraspinal muscles with several trigger points noted and marked tenderness at the level of L4–L5. His reflexes are intact, and he has full strength in his lower extremities. The remainder of his physical examination is unremarkable except that general deconditioning is noted. There are no laboratory tests or imaging studies available. He reports that his blood pressure is usually around 150/80 mm Hg with a pulse around 75 beats/minute.

What are the clinically relevant findings (or absence of findings) for J.P.'s pain assessment, and how would you characterize his pain?

The presentation and assessment of back pain can be very complex given its multifactorial nature. Acute low back problems are defined by the Agency for Health Care Policy and Research as "activity intolerance attributable to lower back or back-related leg symptoms of less than 3 months' duration."[64] J.P.'s acute exacerbation would fit this definition. When J.P. has acute exacerbations of his back pain, the numeric pain scale is an accurate assessment tool (Table 55-2, Fig. 55-4). His rating of 10 out of 10 indicates severe acute pain. Clinicians should also consider a patient's vital signs, which may be elevated with acute pain. If a patient is unable to communicate (e.g., on a respirator), changes in vital signs may be the only indicator of discomfort.

J.P.'s chronic back pain assessment must rely heavily on the history he provides, because there is minimal objective evidence to base the assessment on, other than his findings on physical examination or imaging studies. He indicated that his chronic pain is about 7 out of 10 on the numeric pain scale. Even though the numeric pain scale has been validated for chronic pain, it is less useful in this setting because it only gives a snapshot of the whole pain picture. A multidimensional tool, such as the Brief Pain Inventory or the McGill Pain Questionnaire, is more useful to assess chronic pain (Table 55-2).[18,19] Physical activities, sleep, diet, and social interactions may be affected by chronic pain. J.P. notes that his pain is worse with physical activity. He reports sleeping poorly and has limited physical activity and minimal social interaction. All of these factors contribute to a patient's pain experience and must be considered (Fig. 55-1). Assessment of chronic pain is not only more complex, but is more extensive, because the perception and response to chronic pain is widely variable. Each patient experiences pain in his/her own way. A psychological assessment is essential to identify comorbidities such as depression or anxiety and any history of abuse (e.g., physical, verbal, sexual) or previous trauma, as well as to assess a patient's coping ability. It may be helpful to ask J.P. about his spirituality and cultural values, because these may offer unique opportunities (or barriers) to any proposed treatment plan.

If opioids are being considered, many clinicians endorse the use of a substance abuse screening tool such as the Screener and Opioid Assessment of Patients with Pain-Revised (SOAPP-R), Opioid Risk Tool (ORT), or Diagnosis, Intractability, Risk, Efficacy (DIRE) score.[83] J.P. drinks alcohol, smokes tobacco, and has used his sister's acetaminophen/codeine. These factors may warrant use of a screening tool to assess his risk for opioid abuse.

J.P.'s chronic pain has been present for several years and has gradually worsened. Based on his history and current physical examination, he appears to have mechanical musculoskeletal pain. He is a former plumber, which involves bending and lifting, which puts him at risk for facet joint arthritis. He describes the aching, localized pain that is typical of arthritis, either in his spine–hip junction (sacroiliac joint) or his zygapophyseal (facet) joints, which are the most common locations for lumbosacral pain. He demonstrated localized tenderness at the L4–L5 level. This is most consistent with facet joint disease. He also has tenderness along muscles in his low back, reaching into his buttocks, which is very common, because the body attempts to accommodate structural spine abnormalities. Muscular pain may radiate into the mid-back or into the buttocks, but does not travel below the knees. J.P. did not have pain that radiated below the knees. J.P. does not have any motor weakness, past experiences, or comorbidities that would indicate a red flag (Table 55-9). J.P.'s physical examination reveals radicular pain in the L5 dermatome (i.e., an area of the skin supplied by nerves from a single spinal root). Unlike muscular pain, radicular pain travels from the spine past the knee into the distal extremities. J.P. describes burning and shooting pain that radiates from his spine down his right leg to his toes. These are hallmarks of neuropathic pain. J.P. appears to have both musculoskeletal/myofascial and neuropathic pain. This mixed picture is very common with back pain and adds complexity to both diagnosis and treatment plans.

CASE 55-3, QUESTION 2: What comorbidities will affect J.P.'s presentation and pain assessment?

J.P. has a concurrent diagnosis of depression, which is quite common in patients with chronic pain. The incidence of depression in chronic pain patients is 2 or 3 times higher than the general population.[84] Depression is often under-recognized in the face of pain as a presenting symptom. Many times healthcare providers investigate for a functional cause of the pain, but overlook the psychosocial aspects of pain. Variables associated with depression in chronic pain are female sex, younger age, lower socioeconomic status, unmarried, Caucasian, and higher pain severity.[85] In fact, because pain severity worsens, depressive symptoms worsen, medical visits become more frequent, and healthcare costs increase.[86] The relative deficiency of NE and 5-HT that occur with depression makes the pain-blocking function of the descending pain pathway less effective. As a result, J.P. may feel more pain physiologically and may also have a greater emotional response to his pain and other stressors. His depression may be contributing to his sleep disturbance and his diminished social interactions. Untreated depression may be detected with a multidimensional pain assessment tool. If identified and treated, his pain may improve concurrently with his depression. Other psychiatric comorbidities that commonly occur with chronic pain include anxiety, personality disorders, and substance abuse.

J.P. also has a diagnosis of hypertension. Although this will not directly contribute to his pain, any acute exacerbations may cause an increase in his pulse and blood pressure. Increases in blood pressure are associated with an increased incidence of stroke. The presence of hypertension is also a factor when developing a treatment plan. He is currently taking ibuprofen for pain, and NSAIDs are known to cause fluid retention, compromise renal function, and diminish the benefits of antihypertensives (such as J.P.'s lisinopril). Corticosteroids, which may be used during an interventional pain procedure, may also increase blood pressure.

CASE 55-3, QUESTION 3: How can current low back pain treatment guidelines be applied to J.P.'s pharmacologic regimen?

Acetaminophen is considered first-line therapy for low back pain. J.P. has been using acetaminophen up to 6,000 mg daily, which exceeds the recommended maximum daily dose. He has also been using some acetaminophen/codeine that he obtained from his sister. J.P. is at risk for liver toxicity from high doses of acetaminophen. Additionally, he has not found the acetaminophen to be helpful, so it should be stopped. J.P. is also taking ibuprofen, which is recommended as second-line therapy. He is taking 2,400 mg daily without benefit. His pain relief is unlikely to improve with a dose increase, but he may benefit from rotation to another NSAID with a different chemical structure. Naproxen is an inexpensive agent that is also available over the counter. He does not demonstrate any muscle spasm, so a muscle relaxant is not indicated, nor is it recommended for chronic back pain. He has radicular pain, so a trial of gabapentin may be helpful. He has been using the codeine-containing product and notes that this has been helpful; however, opioids are not recommended for long-term management and have not shown substantial benefit with long-term use. He should be encouraged to reduce or discontinue use of the opioid. Chang et al. recommend a trial of TCAs if NSAIDs and acetaminophen have failed.[87] This may also help his chronic insomnia, but the doses used for analgesia (typically less than 100 mg/day) may not be high enough to have true antidepressant effects. Selective serotonin reuptake inhibitors (SSRIs) may be used to treat depression, but have very little independent analgesic effects. However, if his depression improves, we would expect to see a proportional improvement in his pain. Because SSRIs are better tolerated than TCAs, and TCAs have not demonstrated improvement in function in the long term, J.P. should have a trial of a generic SSRI such as citalopram. SNRI's may also be an effective and well-tolerated option that would treat both his depression and pain.

CASE 55-3, QUESTION 4: J.P. has been taking two different muscle relaxants for his back pain. He reports that neither of these is very helpful, and he usually does not have muscle spasms but does have trigger points on physical examination. What would you recommend with regard to continuing these drugs? Would a trial of a different muscle relaxant be appropriate?

Muscle relaxants are commonly used to treat chronic musculoskeletal pain. They are recommended for short-term use for acute low back pain (all are fairly equal).[69] Chou et al. performed a systematic review of trials to compare efficacy and safety of skeletal muscle relaxants.[70] Although the evidence was considered to be of fair quality, they concluded that for the treatment of musculoskeletal pain, tizanidine, orphenadrine, carisoprodol, and cyclobenzaprine were more effective than placebo. There were not sufficient data of good quality to determine whether metaxalone, methocarbamol, chlorzoxazone, baclofen, or dantrolene was better than placebo for this indication. At this time, guidelines do not recommend chronic use of muscle relaxants for musculoskeletal pain. There is a small study that shows improvement in myofascial pain with tizanidine, but there are no data supporting continued use of carisoprodol or cyclobenzaprine.[88] These agents belong to a chemically diverse family, but all work in the CNS, either in the brain or in the spinal cord. They are categorized as either antispasmodics or antispasticity agents. The antispasmodics are either benzodiazepines (e.g., diazepam) or nonbenzodiazepines (e.g., cyclobenzaprine) and are used for muscular pain and spasms associated with peripheral musculoskeletal conditions. The antispasticity agents reduce spasticity associated with upper motor neuron disorders such as multiple sclerosis (e.g., tizanidine, baclofen) (Table 55-11). Because J.P. has not experienced any improvement in his pain with previous trials of muscle relaxants, switching to another is not likely to yield any improvement in his symptoms, though tizanidine has shown some promise.

CASE 55-3, QUESTION 5: J.P. returns after 3 months with a small improvement in his back pain. He is sleeping a bit better (6 hours/night). He is attending physical therapy sessions, although infrequently. He has been taking citalopram 20 mg by mouth daily for his depression and feels that this is somewhat helpful for his mood. He has been taking naproxen 500 mg by mouth 3 times a day and gabapentin 300 mg by mouth 3 times a day for his pain. Neither of these has provided adequate relief. Another provider gave him a prescription for oxycodone 5 mg/acetaminophen 325 mg one to two tablets every 6 hours as needed. J.P. has been taking two tablets every 6 hours on a regular schedule. This helps his pain (30% improvement and he notes that the addition of the opioid has allowed him to start working part time again as a handy man); however, the relief only lasts 3 to 4 hours, and then he is in pain for another 2 to 3 hours before he can take another dose. He also reports a lot of nausea with this regimen. He has heard about "pain patches" and wonders whether these might be an option for him.

J.P. is getting about 30% improvement with oxycodone/acetaminophen, which is a good response for any analgesic, but the duration of relief is short, and he is having nausea after each dose. He has asked about using a pain patch. What therapy might you suggest to optimize J.P.'s analgesia? Is a pain patch a good choice?

Table 55-11

Oral Muscle Relaxants

Drug	Dose	Adverse Effects	Monitoring/Comments

Antispasmodic			
Cyclobenzaprine	5 mg TID, titrate to 10 mg TID	Dry mouth, constipation, urinary retention, somnolence, confusion, blurred vision	Also available in extended-release formulation
Metaxalone	300 mg TID–QID	GI upset, nausea, vomiting, dizziness, headache, somnolence, hemolytic anemia, leucopenia, jaundice	Contraindicated in anemia, liver impairment, renal impairment Monitor liver function, CBC
Methocarbamol	1,500 mg TID, or 1,000 mg QID	Itching, rash, indigestion, nausea, vomiting, dizziness, headache, nystagmus, somnolence, vertigo, blurred vision, arrhythmias, hypotension, leucopenia, urine discoloration	Monitor heart rate, blood pressure
Orphenadrine citrate	100 mg BID	Syncope, nausea, vomiting, dry mouth, dizziness, blurred vision, palpitations	Monitor CBC, liver function
Chlorzoxazone	500–750 mg TID–QID	Lightheadedness, dizziness, somnolence, malaise, liver toxicity	Monitor liver function
Carisoprodol	250–350 mg TID and at bedtime	Dizziness, headache, somnolence, respiratory depression	Monitor for weakness, dizziness, confusion, misuse, or abuse
Antispastic			
Tizanidine	4 mg TID, titrate to max of 12 mg TID	Hypotension, somnolence, muscle weakness	Monitor blood pressure, liver function
Baclofen	10 mg TID, titrate to max of 20 mg QID	Somnolence, muscle weakness, ataxia	
Diazepam	2 mg TID, titrate to max of 10 mg TID	Respiratory depression, somnolence, weakness	Monitor sedation, respiration, misuse, or abuse Risk of physical dependence

BID, 2 times a day; CBC, complete blood cell count; GI, gastrointestinal; QID, 4 times a day; TID, three times a day.

Although opioids are not recommended for chronic low back pain, J.P. has noted an improvement in pain and function.[89] It would be reasonable to consider continuing his analgesic combination. There are several analgesic options available for patients who are unable to tolerate or ingest solid oral dosage forms (tablets and capsules). It is common for patients with feeding tubes and patients who have maxillofacial surgery to use alternative dosage forms such as oral liquids, topicals, or transdermal products (Table 55-12). J.P. has asked about a pain patch. It is likely that he is referring to either a fentanyl transdermal system or a buprenorphine patch. These agents offer extended delivery options, but are often not cost-effective; therefore, a pain patch may not be the best choice for J.P. Because he is able to take oral medications, it would be most reasonable to rotate to an oral opioid that offers a longer duration of action. When considering product rotation for J.P., it is important to consider drug formulation and availability, route of administration, drug interactions, adverse effects, and cost. The oxycodone/acetaminophen product that he is currently using is not providing an adequate duration of analgesia. He may need to use an extended-release/long-acting (ER/LA) opioid to achieve sustained analgesia. There are many ER/LA opioid formulations available including morphine (tablets, capsules), oxycodone (tablets), hydromorphone (capsules), methadone (tablets), oxymorphone (tablets), hydrocodone (capsules, tablets), buprenorphine (patch, buccal film), and fentanyl (patch). Several of these agents are formulated with abuse-deterrent technologies. Because he is getting good pain relief with oxycodone/acetaminophen, converting to a extended-release formulation of oxycodone seems the most logical choice. J.P. is currently taking eight 5-mg tablets of oxycodone daily (40 mg total per day). This may be directly converted to ER oxycodone 20 mg orally twice daily, with elimination of the short-acting product. If he continues to have nausea after his doses of oxycodone, he may need to rotate to another opioid or use a nonoral route of administration, an antiemetic, or a nonopioid analgesic.

J.P. has been using several different analgesics for his pain, including an NSAID, an anticonvulsant, an antidepressant, and an opioid. These agents will offer pharmacologic activity at several points in the pain pathway (Fig. 55-2) and offer additive analgesic effects.[90,91] However, multimodal therapy also carries the risk of additive adverse effects and possible drug interactions. For example, the anticonvulsant and the opioid may cause additive sedation. The balance between adverse effects and analgesia must be considered with any changes in drug therapy. He is also taking lisinopril. Using an NSAID concurrently with an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin receptor blocker may cause hyperkalemia or acute renal blood flow compromise. A nonacetylated salicylate such as salsalate or diflunisal may offer analgesia with a lower risk potential and fewer adverse effects and drug interactions. They have minimal effects on prostaglandin production.

Table 55-12

Analgesics for Patients Who Cannot Take Solid Oral Dosage Forms

Oral Liquids
Acetaminophen (elixir, liquid, solution, suspension, syrup)
Ibuprofen (suspension)

Naproxen (suspension)
Gabapentin (solution)
Pregabalin (solution)
Carbamazepine (suspension)
Oxcarbazepine (suspension)
Nortriptyline (solution)
Oxycodone (solution)
Hydrocodone/acetaminophen (elixir, solution)
Morphine (solution)
Methadone (solution)
Other Oral Products
Lamotrigine (disintegrating tablet) Fentanyl (mucous membrane lozenge, buccal tablet, buccal film, sublingual)
Buprenorphine (sublingual tablet, buccal film)
Rectal Suppositories
Acetaminophen Indomethacin
Hydromorphone
Morphine
Topicals
Diclofenac (gel) Capsaicin (cream)
Local anesthetics (ointment, gel, cream)
Salicylates (gel, cream)
Transdermal Patches
Diclofenac Lidocaine
Capsaicin
Methyl salicylate
Fentanyl
Buprenorphine

CASE 55-3, QUESTION 6: J.P. returns 6 months later, after seeing a pain specialist and a psychologist. He is now taking gabapentin 1,200 mg by mouth 3 times a day, meloxicam 7.5 mg by mouth once daily, amitriptyline 25 mg by mouth every night at bedtime, and oxycodone controlled-release (CR) 20 mg by mouth twice a day. How should J.P.'s therapy be monitored?

Clinicians must assess each part of J.P.'s care plan, both the positive aspects and the negative aspects. Is J.P. meeting his goals on his personal care plan? Is he getting more sleep? Is he more physically active? Is he managing his stressors better? Is his pain improved? There are several monitoring tools that may be used routinely to record long-term progress. The "5 A's" of monitoring therapy are often used: analgesia, activities of daily living, adverse effects, affect, and potential aberrant drug-related behavior.[92]

In addition to monitoring for efficacy, assessing for adverse effects of his medication is critical. Gabapentin may cause sedation, dizziness, edema, and cognitive impairment of short-term memory, concentration, and word-finding. Meloxicam, an NSAID, may cause GI upset or ulceration, so he should be advised to watch for black, tarry, sticky stools or any sign of internal bleeding. He may experience easy bruising and bleeding related to the platelet inhibitory effects of NSAIDs and should have his serum creatinine and potassium checked regularly to monitor for NSAID-induced renal toxicity. His blood pressure should also be monitored regularly because this has been elevated in the past. Oxycodone may cause constipation, sedation, dry mouth, and urinary retention. If he is using the opioid regularly, he should be advised to also use a bowel regimen with a stool softener, osmotic laxative, or a motility agent. Additionally, if he is using the opioid for an extended period of time, he may need to have his testosterone levels checked and bone density testing done periodically to monitor for hypogonadism and osteoporosis, which are associated with chronic opioid therapy. Amitriptyline may cause additive sedation, constipation, and urinary retention. He is unlikely to have problems with orthostatic hypotension, but this is common in older patients.

CASE 55-3, QUESTION 7: What nonpharmacologic therapies may be beneficial for J.P.'s pain?

Koes et al. found that most guidelines recommend a supervised exercise program, cognitive behavioral therapy, and short-term pharmacologic therapy.[65] The APS recommends that epidural steroid injections and possibly surgery may be considered in patients with persistent radicular low back pain. Because J.P. has radicular pain into his legs and he has tried first-line therapies, he may be a candidate for an epidural steroid injection. This will only offer temporary relief, at best, but may provide him enough relief to participate more in physical rehabilitation. Studies show mixed results with both injections and surgery, so J.P. must be part of the decision-making process.[93]

In the past, patients were advised to use bed rest for acute back pain; it is now recommended that patients remain physically active. This has been shown to improve pain and function at 3 to 4 weeks compared with bed rest.[94] Bed rest is also not recommended for chronic back pain. J.P. still has limited physical activity and was noted to be deconditioned. Inactivity can increase muscular pain. A referral for physical rehabilitation is a key component of management, specifically a supervised exercise regimen. There is no difference in benefit among different forms of exercise, so J.P. and his therapist may build a program that best fits his interests and needs. Physical rehabilitation also may include stretching and strengthening, but these are not effective unless used as part of a comprehensive exercise program. Other modalities such as cold packs to reduce inflammation in the acute phase of an injury and heat to relax muscles may be used, but there is no evidence supporting either of these therapies. Spine manipulation and low back corsets have shown some efficacy, but other physical modalities such as massage, ultrasound, traction, injections, acupuncture, or shoe lifts have not been shown to be effective.[70] J.P. may report that he has more pain after he starts an exercise regimen, because his muscles get reconditioned. J.P. should be encouraged and given assurances that physical activity that is at an appropriate level for his needs may cause him to hurt but will not harm him. He can also learn how to pace his activities so he does not overdo it with yard work as he has done in the past.

Cognitive behavioral therapy (CBT) and mindfulness-based stress reduction (MBSR) have been shown to improve back pain and functional limitations.[95] Mental health care is an essential component of multidisciplinary pain management. CBT works on a patient's perception of pain and expectations, focusing on mood, catastrophizing, negative thinking, and poor coping skills. MBSR focuses on increasing awareness and acceptance of moment-to-moment experiences including physical discomfort and difficult emotions. After J.P.'s depression is addressed, he can work with a therapist on coping skills and how to use self-regulation and manage stressors.

NEUROPATHIC PAIN AND POSTHERPETIC NEURALGIA

Pain may be centrally or peripherally mediated. Peripheral sensory neuropathy usually involves injury or insult to peripheral nerves, like postherpetic neuralgia (PHN), which affects spinal nerve dermatomes. The pain tends to be fairly localized, either regionally or along an associated dermatome. Central pain syndromes originate from injury to the CNS or alteration in central pain processing, as occurs with neuroplasticity. Central pain presents with a larger affected area, up to and including unilateral, head-to-toe pain that may be seen after a stroke.

Herpes zoster occurs in 500,000 Americans each year, and approximately 20% of these patients experience PHN.[96,97] Evidence-based guidelines for treating neuropathic pain have been sponsored by several international organizations in the last several years.[20] Most studies have been conducted in PHN and diabetic peripheral neuropathy (DPN), because these are the most common neuropathic pain conditions. Some types of neuropathic pain (e.g., spinal cord injury and human immunodeficiency virus neuropathy) have been quite resistant to pharmacologic therapy. Studies to date have shown only partial relief of neuropathic pain regardless of pharmacologic treatment. Doses, adverse effects, and monitoring for these agents can be found in Table 55-8.

First-line treatments for neuropathic pain include SNRI antidepressants such as TCAs, venlafaxine, and duloxetine. These antidepressants demonstrate effective pain relief, even in patients without concurrent depression. The TCAs are inexpensive and easily administered once daily; however, they have significant anticholinergic adverse effects, such as dry mouth and constipation that many patients do not tolerate. The secondary amine antidepressants, like nortriptyline, have fewer anticholinergic adverse effects than the parent compound amitriptyline and are similarly effective. TCAs are known to cause orthostatic hypotension and urinary retention in elderly patients and may cause cardiac arrhythmias with higher doses. Venlafaxine functions as an SSRI at low doses and needs to be titrated by 37.5- or 75-mg increments each week to reach a target dose of at least 200 mg daily. At this dose, venlafaxine offers SNRI activity. However, at higher doses (>225 mg/day), increases in blood pressure and heart rate caused by increased NE activity may cause patients to stop therapy. Duloxetine has shown efficacy in treating neuropathic pain with doses of 60 to 120 mg/day.[98] Cardiac rhythm, blood pressure, and pulse rate do not seem to be affected by duloxetine. The most common adverse effect with duloxetine is nausea on initiation and sweating. The dose of duloxetine is titrated up over 2 weeks to minimize the nausea. Duloxetine is contraindicated in patients with liver disease or those who drink alcohol, because there have been reports of liver failure with this medication.[99]

Anticonvulsants that bind to voltage-gated calcium channels are also considered first-line therapies for C fiber-related neuropathic pain (such as DPN and PHN), allodynia, and nonpainful dysesthesias (i.e., abnormal sensations). They have also been very helpful in reducing central sensitization by preventing the release of glutamate and blocking glutamate receptors. Gabapentin and pregabalin (gabapentinoids), both voltage-gated calcium-channel blockers, have shown efficacy and are FDA-approved for treating neuropathic pain, including PHN and DPN.[100–102] These agents must be taken 2 or 3 times daily and may cause dizziness, somnolence, peripheral edema, and cognitive problems. The somnolence is usually managed with a slow titration, but these combined effects may be significant in elderly patients. Although neither agent has many drug interactions, the doses must be reduced for renal insufficiency, because they are mostly renally eliminated.

Anticonvulsants that block sodium channels, such as carbamazepine, oxcarbazepine, and lamotrigine, have been shown to be helpful for A∂ fiber-mediated pain such as trigeminal neuralgia that has sharp, shooting qualities. Carbamazepine is an older agent that requires routine monitoring of complete blood counts (CBCs) for blood dyscrasias, liver transaminases for possible hepatitis, and serum sodium for possible syndrome of inappropriate antidiuretic hormone (SIADH)-induced hyponatremia. It is also a strong cytochrome P-450 enzyme inducer, and there are numerous drug–drug interactions with carbamazepine. Oxcarbazepine has substantially fewer drug interactions and does not require monitoring of CBCs and liver transaminases because it does not form the same

10,11-epoxide metabolite as carbamazepine. It requires monitoring of serum sodium for the first 3 months of therapy and periodically thereafter, because it may cause SIADH and hyponatremia. Lamotrigine has few drug interactions except with valproic acid and does not require any laboratory monitoring. It may, however, cause a desquamating rash (e.g., Stevens–Johnson syndrome) if the dose is escalated too quickly. A newer agent, lacosamide, shows modest efficacy for treating DPN but is not FDA-approved for treating pain.

Topical agents such as local anesthetics and capsaicin are effective for treating localized areas of neuropathic pain, such as PHN. A 5% lidocaine patch is approved by the FDA for the treatment of PHN and is particularly helpful for treating allodynia. It is very well tolerated and easy to apply. It may be cut to the desired shape, and very minimal local anesthetic penetrates the skin, so there is no systemic toxicity with proper administration. Various other topical lidocaine products are available (e.g., ointments and creams), but most do not penetrate the skin deep enough to reach the affected nerve endings. Capsaicin depletes substance P in the periphery and downregulates the transient receptor potential vanilloid 1 (TRPV1) receptors. Because it is derived from chili peppers, it causes a significant amount of burning until the substance P is depleted, and many patients do not tolerate the application of the cream several times daily to accomplish this. Capsaicin cream is available in several strengths, and there is an FDA-approved 8% patch available for medical office use which is applied for an hour under local anesthesia and can be reapplied once every 3 months.[103]

Opioid analgesics have shown moderate efficacy at best in treating neuropathic pain and are not usually considered first-line therapy because of potential long-term effects such as hyperalgesia, tolerance, immunosuppression, and hypogonadism with osteoporosis.[20] Tramadol and tapentadol, atypical opioids, have both opioid activity and SNRI activity and have been shown to be effective in several types of neuropathic pain. Their adverse effects are similar to those of both opioids and SNRIs, including constipation, sedation, and possibly seizures, which are a dose-limiting effect.[20,104]

When compared in a systematic review and meta-analysis, all of the first-line agents and most second-line agents were equally effective with no significant differences in safety.[20]

There are some data that show that a combination of agents, such as an opioid and a gabapentinoid, or a TCA and a gabapentinoid, may offer more analgesia than either agent alone.[90,91] This polypharmacy may offer additive analgesia because different agents act on different parts of the pain-signaling pathways. If more than one agent is used, lower doses of each may reduce adverse effects. However, polypharmacy adds complexity to regimens, which may reduce compliance and cause confusion, particularly in elderly patients.

Postherpetic Neuralgia

CASE 55-4

QUESTION 1: K.J. is a 73-year-old man with a history of Hodgkin lymphoma. He is in remission after chemotherapy and radiation treatment. He is seen in consult for PHN attributable to a case of shingles during chemotherapy. The zoster episode was after his first chemotherapy cycle 2 years ago. The lesions covered an area around his right lower abdomen below the umbilicus in a 10- to 15-cm strip around the lower back and buttock. At rest, his pain is a 1 to 2 out of 10 on the numerical pain scale. At its worst, it is 7 to 8 out of 10. Pain is aggravated by light touch or any jarring motion (such as riding in a car) or rubbing of clothes on the location of the zoster. He has two areas that have greater pain, one located in the lower right aspect of his back and the other in the right lower abdominal quadrant. He describes the pain as a burning sensation. He gets mild relief from topical aquaphilic ointment. If he stays busy, it sometimes takes his mind off the pain. He has not been sleeping well because of the pain. His past medical history includes Hodgkin lymphoma (in remission), low back pain, and benign prostatic hypertrophy (BPH). He currently takes acyclovir 400 mg by mouth once daily, alprazolam 0.25 mg by mouth every night at bedtime as needed for sleep, docusate 100 mg by mouth twice daily as needed for constipation, multivitamin one tablet by mouth once daily, tamsulosin 0.4 mg by mouth every night at bedtime, and zolpidem 5 mg by mouth every night at bedtime. K.J. is married, has never smoked, and denies alcohol and illicit drug use. His physical examination is unremarkable with the exception of scarring noted from the right lower abdomen to the back. Laboratory results and vital signs obtained at this visit are the following:

Serum creatinine, 1.2 mg/dL
Electrolytes, within normal limits
Blood pressure, 137/80 mm Hg
Heart rate, 77 beats/minute
Weight, 80 kg

Which of K.J.'s presenting symptoms are consistent with neuropathic pain and PHN?

K.J. is past the acute phase of his herpes zoster (shingles) pain, but now notices that the pain has a burning quality, localized over the region where his lesions have healed. This is quite typical for a PHN presentation. Another feature that indicates a neuropathic type of pain is his increase in pain with light touch or rubbing of his clothing (allodynia). It is a localized pain that does not radiate past the dermatomal distribution of his zoster infection. Opportunistic infections such as herpes zoster are common in patients who are immunocompromised such as K.J. when he was receiving chemotherapy.

CASE 55-4, QUESTION 2: What factors need to be considered when choosing a medication for K.J.? Which medication is the most appropriate option for treating K.J.'s PHN pain?

POSTHERPETIC NEURALGIA TREATMENT

The American Academy of Neurology (AAN) published PHN treatment guidelines in 2004. Since that time, there have been many more studies published, but there has been very little change in the approach to treating neuropathic pain. The AAN guidelines state that TCAs (e.g., amitriptyline, nortriptyline, and desipramine), gabapentin, pregabalin, opioids, and topical lidocaine patches are effective and should be used in the treatment of PHN.[105] The International Association for the Study of Pain has also published guidelines on the general treatment of neuropathic pain.[20]

Ideally, patients should be treated with the most effective therapy that has the lowest risk of adverse effects. K.J. has peripheral neuropathic pain in a localized area, which is typical of PHN, so a reasonable first-line choice would be a lidocaine patch; however, his pain is in a 10- to 12-cm strip that covers a fairly large surface area from his abdomen to his back. He would need to use at least two patches daily to cover this area, which is fewer than the maximal recommended dose of three patches daily, but it would be an effective barrier against the pain of clothing rubbing against this location. Another localized option would be capsaicin (either as a patch or a cream). Capsaicin cream is available over the counter and is substantially less expensive than lidocaine patches. Insurance plans may require a trial of capsaicin before approving the more expensive lidocaine patch. Unfortunately, many patients cannot tolerate the burning associated with capsaicin.

Another first-line option would be a TCA, which may help him sleep. However, he has BPH, and the anticholinergic effects of a TCA may cause increased urinary retention. These medications also cause orthostatic hypotension and may be a risk for K.J. if he has to get up during the night to use the bathroom (Table 55-8). An SNRI such as duloxetine would have fewer anticholinergic adverse effects but is not FDA-approved for treating PHN.

A calcium-channel blocking anticonvulsant such as gabapentin is also a possibility. The sedating effects of gabapentin may help him sleep if his last dose is given at bedtime, and would not cause the urinary retention, constipation, and orthostatic hypotension associated with TCA use. Given his age, a slow dose escalation starting at 100 mg by mouth 3 times a day would be appropriate. The most important aspect of monitoring for this agent would be for cognitive effects, such as short-term memory problems or difficulty with word-finding.

If the above options do not provide adequate analgesia, addition of an opioid such as morphine or oxycodone may be considered due to the potential for additive analgesia. Initially, a short-acting opioid should be used so that K.J. may be titrated to the optimal analgesic dose. Tramadol is another alternative with some TCA-like activity and mild opioid effects. However, if an opioid is added, it may increase the adverse effects of the above agents, including constipation, sedation, urinary retention, and cognitive effects. Whenever an opioid is added to a medication regimen, a bowel regimen must be implemented as well. A commonly used regimen includes a stool softener such as docusate sodium 100 mg by mouth twice daily or an osmotic agent such as polyethylene glycol 17 g by mouth daily and a mild stimulant laxative such as senna 8.6 mg one to two tablets by mouth once daily.

CASE 55-4, QUESTION 3: K.J. returns after 2 months with complaints that he could not tolerate the burning of the capsaicin cream so discontinued this. He is currently taking gabapentin 1,200 mg by mouth three times daily and tramadol 50 mg one tablet by mouth four times daily. He continues to have 5 of 10 burning pain over his right abdomen and back. He states that he has felt drowsy and has “unclear thoughts” with the gabapentin and does not feel that it has been very effective, despite titrating this to the maximal dose of 3,600 mg daily. His wife reports that he is withdrawing from friends and he does not feel as involved. He is sleeping better, however, and believes that the tramadol is somewhat helpful in "taking the edge off" his pain. Given this information, what would be an appropriate adjustment in his therapy?

MODIFYING THE NEUROPATHIC PAIN REGIMEN

Adverse cognitive effects like K.J. is having are common with anticonvulsants, especially in older patients. Problems with memory, concentration, and word-finding are common. No anticonvulsant is better than any other in this regard; however, some of the adverse effects are dose-related, and patients may exhibit tolerance to some of the effects (like sedation) with time. K.J. is at the maximal recommended daily dose of gabapentin and does not feel that this has been very helpful. At this time, he may need to be tapered off the gabapentin. Sometimes patients do not notice analgesic effects of their medications until they are discontinued. It is a good practice to titrate oral analgesics upward when starting therapy and downward when discontinuing, to avoid a marked increase in pain and withdrawal syndromes that have been reported with both antidepressants and some anticonvulsants. He could reduce his dose by 300 mg every 3 to 5 days until his pain increases or he is off the gabapentin.

A different topical agent would be the lidocaine patch. Because he and his wife are reporting some signs of depression, an antidepressant may be an option. An antidepressant was not chosen previously because of concerns about his BPH symptoms; however, a nontricyclic SNRI agent such as duloxetine may be an effective alternative to treat his depression as well as his pain, although there are no studies reporting its effectiveness for this indication. Another option may be to switch to another anticonvulsant. Pregabalin has very similar pharmacologic activity to gabapentin, so it may not offer any additional analgesia over gabapentin. Possibly, a sodium-channel blocking anticonvulsant such as oxcarbazepine could be used for a trial. However, there are minimal data supporting the sodium-channel blockers for typical C fiber-mediated pain associated with PHN.

CASE 55-4, QUESTION 4: K.J.'s doctor decides to order duloxetine and a lidocaine patch and taper off the gabapentin as tolerated. When the doctor orders K.J.'s new regimen, a drug–drug interaction listed between duloxetine and tramadol is identified. What recommendations are appropriate with regard to the potential drug–drug interactions with analgesics and, in particular, with K.J.'s regimen? What changes to his regimen could be suggested?

ANALGESIC DRUG–DRUG INTERACTIONS

Antidepressants either increase the concentrations of NE or 5-HT or both. Opioids also have serotonergic effects, so it is possible to have a net excess of either of these neurotransmitters, or both. The consequence of an excess of NE is CNS excitation and possible seizures. The consequence of an excess of 5-HT is a possibly life-threatening syndrome called serotonin syndrome. Symptoms of serotonin syndrome include muscle rigidity, hyperpyrexia, mental status changes, and possible organ failure. None of these serious adverse effects are very predictable, although they are more likely with higher doses of either agent. If opioids are used with antidepressants, the lowest effective doses should be used, and patients should be counseled to watch for mental status changes.

Pharmacodynamic interactions are more likely to occur with analgesic polypharmacy. Because several analgesics may be used together to decrease the excitatory effects of the pain signal, there is always a risk of additive sedation, dizziness, or even respiratory depression. Several pharmacokinetic drug–drug interactions may occur with analgesics as well. In K.J.'s case, his duloxetine and tramadol are both substrates of cytochrome P-450 2D6 and may compete with each other for this enzyme. This may alter the blood levels and clinical effects of these agents. A table of agents commonly used in pain management, the relevant cytochrome P450 enzyme involved in its metabolism, and potential drug interactions can be found in Table 55-13. K.J. likely needs an antidepressant for his depression symptoms, so alternatives will need to be considered.

Table 55-13

Drug Interactions with Analgesics

CYP1A2	CYP2C9	CYP2C19	CYP2D6	CYP3A4
Substrates				
Amitriptyline	Amitriptyline	Amitriptyline	Amitriptyline, mexiletine	Alprazolam, methadone
Naproxen	Celecoxib	Citalopram	Nortriptyline, morphine	Amitriptyline, prednisone
R-warfarin	Diclofenac	Diazepam	Cyclobenzaprine, codeine	Buspirone, sertraline
Duloxetine	Fluoxetine	Indomethacin	Desipramine, oxycodone	Clonazepam, temazepam
Methadone	Ibuprofen	Topiramate	Doxepin, paroxetine	Codeine, zaleplon
Theophylline	Naproxen		Fluoxetine, sertraline	Cyclobenzaprine, zolpidem
Tizanidine	Piroxicam		Hydrocodone, tramadol	Diazepam, R-warfarin
	S-warfarin		Methadone, venlafaxine	Fentanyl, carbamazepine
	Phenytoin		Fentanyl, duloxetine	Lidocaine, erythromycin
Inducers				
Carbamazepine	Carbamazepine	Carbamazepine	Carbamazepine	Carbamazepine

Phenytoin	Fluoxetine	Phenytoin	Phenytoin	Oxcarbazepine
	Cimetidine			Phenytoin
	Metronidazole			
	Fluconazole			
Inhibitors				
Cimetidine	Carbamazepine	Fluoxetine	Celecoxib	Fluoxetine
Ciprofloxacin	Paroxetine	Indomethacin	Desipramine	Sertraline
	Sertraline	Paroxetine	Fluoxetine	Ketoconazole
	Valproic acid	Topiramate	Methadone	Cyclosporine
	Phenytoin		Paroxetine	
			Sertraline	
			Valproic acid	

CYP, cytochrome P-450.

CENTRAL NEUROPATHIC PAIN: POSTSTROKE PAIN

Pain is one of the most distressing symptoms after a stroke. As mentioned previously, poststroke pain is a central pain syndrome, caused by a lesion in the CNS. Sometimes the cause of central pain syndromes cannot be identified, and even though a stroke presents with a specific lesion, it is still very difficult to treat. There are several different types of pain after a stroke and patients may have more than one type. Nociceptive pain may be related to immobilization, spasticity, and/or muscle contraction in the event of limb paresis. The shoulder is the most common location but musculoskeletal/myofascial pain can occur in the upper back and neck, as well as tension-type headache. The lower extremities may be affected by weakness, muscle spasms, and/or arthralgias from joint disuse. However, by far the most difficult and far-reaching pain is central neuropathic pain generated in the CNS, which is called central poststroke pain (CPSP). CPSP has been reported in as many as 1% to 18% of stroke survivors.[106] The diagnostic criteria for CPSP are as follows: (1) pain within an area of the body corresponding to the lesion of the CNS; (2) history suggestive of stroke and onset of pain at or after stroke onset; (3) confirmation of a CNS lesion by imaging or negative or positive sensory signs confined to the area of the body corresponding to the lesion; and (4) other causes of pain, such as nociceptive or peripheral neuropathic pain, that are excluded or considered highly unlikely.[107] The clinical presentation of CPSP is similar to other neuropathic pain. The onset of pain ranges from immediate to several months after stroke. It may affect a small region of the body or a large area (from head to toe). Central pain after a contralateral stroke is quite common, particularly after thalamic strokes (e.g., patients with a stroke in the left side of the brain will have symptoms on the right side of the body). Because the thalamus is the brain's "relay station," any abnormal signaling may be amplified.[108] Temperature-sensory dysregulation via the spinothalamic tract is common, as well as dysesthesias and allodynia. It is described as "burning," "aching," "squeezing," "pricking," or "cold." These symptoms are frequently aggravated by a cold environment, psychological stress, heat, fatigue, or body movement.

Treatment of CPSP

There are no guidelines for management of CPSP, and few robust studies exist but lack data related to comparative efficacy. Therapy is usually done on a trial and error basis. Current data support use of amitriptyline (with titration from 10 mg/day up to 100 mg/day) as first-line therapy.[109] Nortriptyline may be used as an alternative TCA in patients who do not tolerate amitriptyline. SNRIs have been shown to be beneficial for other types of neuropathic pain but not for CPSP. If pain relief is insufficient, an anticonvulsant may be used. Lamotrigine (titrated to 400 mg/day) may be added or exchanged for the TCA. It has been shown to have some efficacy for CPSP and was fairly well tolerated.[110] Other anticonvulsants that have shown efficacy for both central and peripheral neuropathic pain are listed in Table 55-8.[111] Opioids have been studied in patients with CPSP but were not effective, and there was a high withdrawal rate.[112] Other therapies such as intravenous infusions of lidocaine, morphine, and ketamine are only experimental and are not recommended. It is not unusual to combine agents with different mechanisms of action, though there are no data supporting this for CPSP. Monotherapy should be titrated to the maximum recommended dose.

Nociceptive pain such as shoulder pain related to stroke may be treated with acetaminophen or local/topical agents. NSAIDs are contraindicated due to the increased risk of myocardial infarction and stroke; however, salicylates may be considered. Muscle spasms or spasticity is common after a stroke, and this is usually treated with an antispasticity agent such as baclofen or tizanidine. Skeletal muscle relaxants are generally not effective for long-term use.

Nonpharmacologic therapies for CPSP include deep brain stimulation, motor cortex stimulation, and transcranial magnetic stimulation. Physical rehabilitation (physical and occupational) is essential to help improve function and cognitive behavioral therapy is used to help patients cope with their new circumstances and cognitive or physical limitations.

CASE 55-5

QUESTION 1: W.J. is a 50-year-old man with a history of a right cerebellar ischemic stroke 4 years ago. He initially presented with sudden onset neck pain, nausea, vomiting, and dizziness. Since his stroke, he has had body tingling including all four extremities and his spine. He also has some localized throbbing pain in his neck and headaches. He reports some spontaneous jerking and muscle spasms that affect his extremities (mostly the right side) and sometimes down his back. He notes some right side weakness as well with muscle atrophy. He also describes chronic tinnitus, dizziness, and headache with sharp eye pain (vision is normal per recent eye examination). He has chronic intermittent nystagmus described as eye "throbbing" when looking to the periphery on either side. He has headaches several times a week (frontotemporal and unilateral). Phono- and photophobia are significant when they occur. He has nausea, but rarely emesis. He reports increased pain with cold weather and stress.

He has a past medication history of HTN, type 2 diabetes mellitus, and depression. He takes aspirin 325 mg by mouth daily, insulin glargine 72 units subcutaneously every morning, insulin lispro sliding scale subcutaneously 3 times daily, atorvastatin 20 mg by mouth every night at bedtime, and sertraline 200 mg by mouth once daily. He does not drink alcohol but is a former smoker (quit 5 years ago). He used to work in a factory but had to quit because he fell several times at work. MRI of the neck showed only a mild disc bulge at C5–C6.

He was holding his head in his hands, wincing periodically. Otherwise his physical examination was unremarkable.

He had reduced vibratory sensation in toes and feet to ankles. His neck was tender to palpation and he had some reduced range of motion. His gait was normal but slow but reports being very unsteady on his feet. His vital signs today are as follows:

Blood pressure, 126/75 mm Hg
Heart rate, 72 beats/minute
Respiratory rate, 16 breaths/minute
Weight 149 kg
His pain rating is 9 out of 10.
What symptoms does W.J. have that are consistent with CPSP?

Although W.J. does not have shoulder pain which may be present in CPSP, W.J. has some localized neck pain. He does not have any obvious injury (e.g., from a fall). Because he has not been very active, and he sits with his head in his hands or bowed forward, his neck pain is most likely myofascial. He has frequent headaches that he localizes to his frontotemporal area.

Because W.J.’s stroke was in his cerebellum, he has notable problems with balance and vertigo as well as tinnitus. These are not painful but are disturbing and limit his functionality and predispose him to falling, which may cause injury. He has intermittent nystagmus which he describes as throbbing. His vision and hearing were within normal limits so his symptoms are sensory only.

Since his stroke, W.J. has had body tingling affecting all four extremities. He reports some spontaneous jerking and muscle spasms that affect his extremities (mostly the right side) and right-sided weakness as well, with some muscle atrophy, and he reports that this is his most painful and bothersome symptom; however, on physical examination there is not notable spasticity. He was noted to have decreased vibratory sensation in his feet and ankles bilaterally. The bilateral presentation is more consistent with his diabetes. He describes more pain with changes in the weather and stress, but this is not specific for CPSP.

CASE 55-5, QUESTION 2: Considering W.J.'s comorbidities, what should be recommended for treating his pain?

Treatment goals for W.J. and any stroke patient are to (1) reduce discomfort and suffering, (2) improve or regain as much function as possible, and (3) improve coping. Because there is so little known about what causes CPSP, it is difficult to tailor analgesic therapy. W.J. has diabetes with symptoms suggestive of diabetic neuropathy. Amitriptyline is considered a first-line therapy for CPSP as well as diabetic neuropathy. Tricyclic antidepressants are also used for depression (though at a higher dose) and for headache prophylaxis. It is unknown whether the anticholinergic effects of the TCA will affect his balance issues, because it may cause orthostatic hypotension. Of concern is his current use of a rather high dose of sertraline. SSRIs do not offer any significant analgesia, and the SSRI and TCA combination will provide additive serotonergic effects, putting W.J. at risk for serotonin syndrome (Table 55-13). A discussion with his mental healthcare provider is warranted to review potential analgesic options, including a trial of an SNRI such as duloxetine. Alternatively, the gabapentinoids may be helpful for his diabetic neuropathy, though there is less support for CPSP. Lamotrigine is likely a slightly more effective choice for CPSP, but lacks robust data for use in diabetic neuropathy. There do not appear to be any drug interactions or contraindications for either type of anticonvulsant.

W.J. has some musculoskeletal neck pain and may benefit from a trial of acetaminophen or salicylates or a topical analgesic; however, NSAIDs are contraindicated due to his history of stroke. He also has some intermittent muscle spasms that are quite bothersome for him. Typically, the antispasticity agents are useful so he may benefit from a trial of tizanidine or baclofen (Table 55-11). Nonpharmacologic therapies such as heat, massage, and physical therapy may be most effective.

FUNCTIONAL PAIN SYNDROMES (FPS)

Functional pain syndromes are a cluster of disorders for which the pathophysiologic mechanisms have not been clearly defined to explain the symptoms.[113] FPS includes medically unexplained symptoms for both gastrointestinal and nongastrointestinal disorders such as dyspepsia, irritable bowel syndrome, fibromyalgia, chronic fatigue, and interstitial cystitis. There can be overlap in the syndromes with the presentation of chronic pain and associated psychiatric comorbidities including depression, anxiety, and posttraumatic stress disorder (PTSD).[114,115]

Pain that does not conform to anatomic or neurophysiologic findings is often attributed to psychopathology. Somatic symptom disorder (SSD) is a diagnostic entity in the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders that replaced somatoform disorder terms including pain disorder, somatization disorder, and undifferentiated somatoform.[116] Somatic symptoms associated with significant distress and disruption of daily life are common with FPS. Patients with FPS often have health concerns manifested by disproportionate and persistent thoughts of serious symptoms, a high level of anxiety about symptoms, and excessive time and energy devoted to health concerns.[116,117]

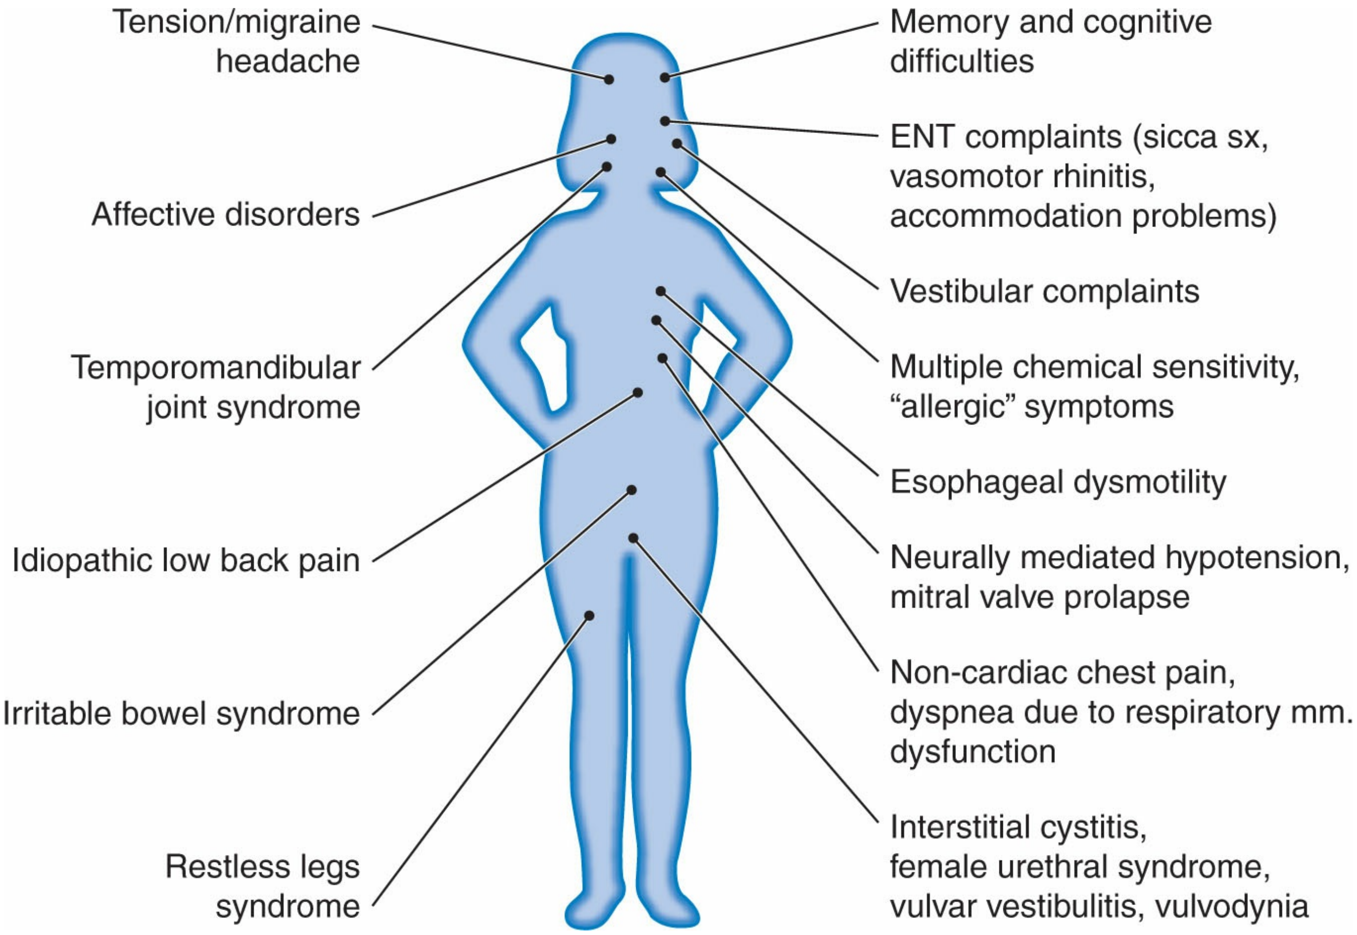
Fibromyalgia is a chronic debilitating condition with the primary symptoms of chronic widespread pain and fatigue. It affects between 3 and 6 million people in the United States, an incidence of 4.9% in women and 2.9% in men.[118] Out of pocket healthcare costs for patients with fibromyalgia is 3 times those without fibromyalgia.[119] It is defined by the American College of Rheumatology (ACR) as pain that is both chronic (lasting longer than 3 months) and widespread (above and below the waist and on both sides of the body). The ACR has published new diagnostic criteria in 2010. They propose using a widespread pain index, in which patients indicate how many areas of their body have pain, and a symptom severity scale, in which patients rate the severity of fatigue, waking unrefreshed, and cognitive and somatic symptoms.[120] Fibromyalgia was previously thought to be peripherally mediated pain related to an inflammatory or muscular disorder, but it has been shown that it may be the manifestation of CNS neurotransmitter dysfunction. Patients with fibromyalgia are more likely to have suffered a traumatic event previously, such as a motor vehicle accident or childhood sexual abuse.[121] Studies have shown an imbalance in neurotransmitters in which excitatory neurotransmitters in the CNS of fibromyalgia patients are increased, including glutamate (a twofold increase) and substance P (a threefold increase), and inhibitory neurotransmitters, NE and 5-HT, are decreased. Patients with fibromyalgia have an enhanced perception of pain at substantially lower forces and at a lower frequency of stimulation than control patients. Pain sensation has a greater amplitude and is more prolonged.[122] Input may be from the periphery or may be triggered by a central stimulus such as a stressor.[123] Heightened sensitivity to lower stimulus seems to contribute to the persistent pain with these patients.[124] This can be widespread and symptoms seem to be largely affected by an exaggerated response to personal stressors, noxious stimuli (hyperalgesia), and non-noxious sensory stimuli (allodynia). Fibromyalgia, as a functional pain syndrome, is associated with other comorbidities that need to be addressed for symptom management, even though treating these symptoms may not directly benefit the hallmark tenderness associated with the syndrome. The assessment tool most often used to assess the impact of fibromyalgia on daily life and function is called the Fibromyalgia Impact Questionnaire (FIQ) (Fig. 55-6).[125]

Fibromyalgia

CASE 55-6

QUESTION 1: G.R. is a 38-year-old woman who presents with chronic widespread muscle pain from her neck down past her buttocks. She also has headaches when her pain is severe. She has had this pain for several years and notes that her pain developed after a car accident in which she sustained a whiplash injury. She describes difficulty sleeping, poor concentration, and fatigue. Her pain rating is 8 out of 10 on most days. She works part time doing some home transcription. She has not identified anything that helps her pain, and physical activity makes the pain worse, so she does not exercise. Her pain is also worse when she is stressed. She was previously told that she has fibromyalgia, and while others have told her that "it's all in her head." Her past medical history includes depression and IBS. She has tried ibuprofen, cyclobenzaprine, carisoprodol, and acetaminophen in the past without relief. She is currently taking tramadol 50 mg by mouth 4 times daily, which provides about 20% pain relief. She is also taking sertraline for depression. G.R. is married and has three children. She smokes one pack of cigarettes daily but denies drinking alcohol or using illicit drugs. She reports that her mother and sister have fibromyalgia and depression. She reports diffuse tenderness to palpation along her paraspinal muscles bilaterally, as well as her bilateral trapezius and levator scapulae muscles and her hips bilaterally. Several tender points are elicited. Her only remarkable laboratory result is vitamin D, 24 ng/mL (normal >30 ng/mL).

What part of G.R's presentation supports the presence of a functional pain syndrome?



Tension/migraine headache
Affective disorders
Temporomandibular joint syndrome
Idiopathic low back pain
Irritable bowel syndrome
Restless legs syndrome
Memory and cognitive difficulties
ENT complaints (sicca sx, vasomotor rhinitis, accommodation problems)
Vestibular complaints
Multiple chemical sensitivity, "allergic" symptoms
Esophageal dysmotility
Neurally mediated hypotension, mitral valve prolapse
Non-cardiac chest pain, dyspnea due to respiratory mm. dysfunction
Interstitial cystitis, female urethral syndrome, vulvar vestibulitis, vulvodynia

Figure 55-6 Systemic conditions that overlap with fibromyalgia. (Reprinted with permission from Clauw DJ. Fibromyalgia. In: Fishman SM et al, eds. Bonica's Management of Pain. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2010:474.)

G.R. likely has fibromyalgia, given her widespread pain that has been present for more than 3 months and was precipitated by a traumatic event (car accident). She reports sleeping poorly, fatigue, and the comorbidities of depression and IBS. On physical examination, she exhibits widespread musculoskeletal tenderness including, but not limited to, several of the identified fibromyalgia tender points, bilaterally, both above and below the waist. Her vitamin D level represents a mild deficiency.

CASE 55-6, QUESTION 2: What pharmacologic and nonpharmacologic therapies could be recommended for G.R.?

There have been several evidence-based guidelines published for the treatment of fibromyalgia.[126–130] These guidelines recommended a multidisciplinary approach with pharmacologic and nonpharmacologic therapy. Because evidence indicates a CNS neurotransmitter imbalance, the most effective pharmacologic approaches have targeted these imbalances. Antidepressants have been shown to reduce pain and improve function by increasing levels of 5-HT and NE in the CNS. Historically, the tricyclics (most commonly amitriptyline) have been shown to moderately improve pain, sleep, and to a smaller extent on fatigue and health-related quality of life (HRQOL). SSRIs have also shown some improvement in pain, depression, and HRQOL but the effect sizes were quite small.[131] Duloxetine and milnacipran are both SNRIs that are FDA-approved for fibromyalgia. Milnacipran appears to have more NE activity than duloxetine. This difference does not appear to confer a therapeutic difference. Both of these agents improve average pain scores, FIQ scores, physical functioning, and overall sense of well-being (Table 55-14).[132,133]

Gabapentinoids have been shown to reduce the activity of excitatory neurotransmitters, particularly glutamate. Pregabalin is an anticonvulsant that was approved by the FDA in 2007 for treating fibromyalgia. It targets the increased levels of glutamate in the CNS by binding to the $\alpha_2\delta$ subunit of voltage-gated calcium channels, preventing release of glutamate from presynaptic terminals (Fig. 55-3). This agent has been shown to improve average pain scores and patient perception of improvement, but failed to show improvement in FIQ scores.[134,135] A long-term open-label study found that patients who did well in the short term maintained an improvement in pain for up to 6 months compared with placebo.[136] Gabapentin, a similar compound, has not been formally approved for fibromyalgia but has support for its use. Some insurance companies require a trial with gabapentin before allowing use of pregabalin because of its lower cost.[137] Hauser et al. compared duloxetine, milnacipran, and pregabalin in fibromyalgia and found that duloxetine and pregabalin were better than milnacipran in improving pain and sleep.[138] Duloxetine was better for symptoms of depression, and pregabalin and milnacipran were better for fatigue. Headache and nausea were more common with duloxetine and milnacipran, and diarrhea was more common with duloxetine.

Other drug therapies that have shown some benefit in treating fibromyalgia and its comorbidities include pramipexole, a dopamine agonist, which is beneficial in treating restless legs symptoms, as well as pain and fatigue.[139] NSAIDs, acetaminophen, and opioids are not recommended for treating fibromyalgia pain.[126–130] In fact, Goldenberg, et al. conducted a literature review and found no evidence from clinical trials that opioids are effective for the treatment of FM. The studies reviewed found that patients with FM receiving opioids had poorer outcomes than those receiving nonopioids.[140] More recently, data have been published noting the effectiveness of low-dose naltrexone, an opioid Mu-receptor agonist, in pain reduction, as well as improvement in general satisfaction with life and mood.[141]

An appropriate first step for G.R. is to develop a multidisciplinary approach, including physical rehabilitation, CBT, and pharmacologic therapy adjustments. She is currently taking an antidepressant (sertraline), which may be helpful for her depression but is likely not very helpful for her fibromyalgia. It may be possible to switch her to an SNRI such as duloxetine or milnacipran in consultation with her mental healthcare provider. She is currently taking tramadol with some relief. She has not maximized her dose (maximum daily dose is 400 mg); however, she is also taking an SSRI, which may place her at a higher risk of serotonin syndrome. The risks and benefits of combining antidepressants with tramadol must be considered on a patient-by-patient basis. Because she is having trouble sleeping, she could be offered a trial of amitriptyline or pregabalin, both of which have sedating side effects (Table 55-7). Pregabalin is a recommended agent and has a different mechanism of action than the medications that she has previously tried. If cost of therapy is a concern, then gabapentin could be tried instead. A vitamin D supplement should also be considered to correct her slightly low vitamin D levels. There is not strong evidence supporting vitamin D supplementation, but there is little harm in correcting her slight deficiency.

Table 55-14

Pharmacologic Treatment of Fibromyalgia

Drug	Oral Dose	Adverse Effects	Comments
Amitriptyline	25–50 mg QHS	Dry mouth, constipation, urinary retention, orthostatic hypotension, somnolence	Caution in elderly patients
Cyclobenzaprine	10–30 mg QHS	Dry mouth, constipation, urinary retention, somnolence	Caution in elderly patients
Duloxetine[a]	30 mg daily × 1 week, then 60 mg daily	Nausea, dry mouth, constipation, fatigue, sweating, anorexia	Monitor liver transaminases
Milnacipran[a]	12.5 mg × 1 day, then 12.5 mg BID × 2 days, then 25 mg BID × 4 days, then 50	Nausea, headache, constipation, insomnia, hot flushes	Monitor blood pressure, heart rate

	mg BID, may titrate to 100 mg BID		
Pregabalin[a]	75 mg BID, titrate to 150 mg TID	Somnolence, dizziness, edema, cognitive effects	Reduce dose for renal impairment
Gabapentin	300 mg QHS, titrate to 600 mg TID	Somnolence, dizziness, edema, cognitive effects	Reduce dose for renal impairment

[a]Food and Drug Administration–approved to treat fibromyalgia.

BID, 2 times a day; QHS, every night at bedtime; TID, 3 times a day.

Bernardy et al. conducted a systematic review of CBT for fibromyalgia and found that this therapy improves coping with pain and reduces depressed mood and health-care-seeking behavior.[142] Hauser et al. evaluated different regimens of aerobic activity with a meta-analysis and found that land- and water-based aerobic exercise, at a slight to moderate intensity, 2 to 3 times a week for at least 4 weeks resulted in improvement of depressed mood and increased health-related quality of life scores and physical fitness. This was maintained if the patient continued exercise at home.[143] Aquatic training is beneficial for improving wellness, symptoms, and fitness in adults with fibromyalgia.[144] Luciano et al found that CBT is more cost-effective that routine FDA-approved medications for adult FM patients.[145]

Psychological Comorbidity and Opioid Risk Management

CASE 55-7

QUESTION 1: M.T. is a 33-year-old woman with chronic abdominal pain. She first experienced recurrent episodes of abdominal pain at the age of 13 after menarche. At age 21, she was diagnosed with acute pancreatitis secondary to alcohol use. Her pain has persisted despite numerous trials of medications including gabapentin, sertraline, tramadol, and hydrocodone/acetaminophen. She has undergone multiple diagnostic evaluations for the abdominal pain, but all have resulted in negative findings. During the past year, M.T. has had eight visits to the emergency department for severe pain where she usually receives IV hydromorphone and then is discharged with a week's supply of oxycodone/acetaminophen. In addition to the emergency department visits, she has been hospitalized 3 times in the past year for abdominal pain.

Today, M.T. is being seen in the clinic by her primary care physician for continued management of chronic abdominal pain, which she describes as "constantly aching." Over the past 2 years, M.T.'s primary care physician has been prescribing oxycodone in conjunction with an opioid agreement focused on minimizing the use of emergency department visits for pain management. M.T. believes her current management with oxycodone 5 mg by mouth every 4 hours as needed for severe pain is insufficient and would like the 30-day supply limit increased from 180 to 240 tablets.

The primary care physician is concerned about M.T.'s functional status since starting opioid therapy. There has been no noticeable improvement in M.T.'s pain despite three increases in the 30-day oxycodone supply over the past 2 years. During the office visit, M.T. is emotionally labile at times and tearful when discussing her pain but is emphatic that she is not depressed. She states that she drinks one or two "highballs" (whisky and soda) about 2 times a week to help her relax when she is feeling "stressed out." M.T. denies smoking or illicit drug use. She is currently unemployed and seeking permanent disability because the pain interferes with her ability to work. Her physical examination is unremarkable except for diffuse abdominal tenderness.

What is the clinical relevance of M.T.'s self-description of abdominal pain?

Clinical Relevance of Abdominal Pain

M.T.’s self-report of pain is consistent with functional abdominal pain (FAP). FAP is more common in women and peaks around the fourth decade of life. Patients with FAP have high work absenteeism and healthcare utilization.[114,146] Key features in the diagnosis of FAP include abdominal pain that is present for at least 6 months and is not related to gastrointestinal function. The patient will often have a decrease in daily activity with time. The principal criterion differentiating FAP from other gastrointestinal disorders, such as pancreatitis, is constant pain that lacks symptom relationship to food intake or defecation. Psychological disturbances are more likely when pain has persisted for a long period and manifests as symptom-related behaviors that dominate a patient’s life (Table 55-15).[117,146]

Table 55-15

Symptom-Related Behaviors of Functional Abdominal Pain

Expressing pain of varying intensity through verbal and nonverbal methods
Urgent reporting of intense symptoms disproportionate to available clinical and laboratory data
Minimizing or denying a role for psychosocial contributors, anxiety, depression; attributing symptoms of anxiety or depression to presence of pain
Requesting diagnostic studies or surgery to validate the condition as “organic”
Focusing attention on complete relief of symptoms
Seeking healthcare frequently
Taking limited personal responsibility for self-management
Making requests for narcotic analgesics when other treatment options have been implemented

From the physiologic perspective, M.T.’s abdominal pain most likely originated from a combination of somatic and visceral components associated with menses and pancreatitis. When the pain symptoms occur frequently in conjunction with a stressor as in FAP, the main mechanism for altered pain regulation relates to the failure to inhibit the amplification of normal regulatory afferent input from the gut to central mechanisms in the prefrontal, cingulated cortex, and limbic structures (e.g., cognitive and emotions centers of the brain). This impairment in homeostatic inhibition of pain may be related to low levels of 5-HT, NE, endorphin, and other neuropeptides that mediate descending pain transmission in the CNS. Recognition of the brain–gut axis in FAP is essential to understanding its clinical presentation, diagnosis, and therapeutic strategies.[15,113]

FUNCTIONAL ABDOMINAL PAIN TREATMENT

CASE 55-7, QUESTION 2: What are the current recommendations for pharmacologic treatment of FAP? What approaches to the management of FAP are appropriate for M.T.?

Pharmacotherapy for patients with FAP is empirical and not based on results from well-designed clinical trials. Clinical trials have not been targeted to this diagnostic entity, so treatments are typically designed on the basis of data from other chronic pain disorders. The cornerstone to management depends on an effective relationship between the clinician and patient. In this case, the primary care physician needs to listen to M.T.'s concerns but set realistic and consistent limits when ordering tests, medical interventions, and medications. M.T. needs to be an active participant in the pain management plan and take responsibility for self-care.[117,146]

Antidepressants, such as TCAs in low daily dosages, may be useful in treating FAP for both pain and depression owing to their combined noradrenergic and serotonergic effects.[147] In other chronic pain conditions, TCAs generally have been more successful than using SSRIs.[128] Medications with combined 5-HT and NE reuptake activity (e.g., SNRIs such as venlafaxine and duloxetine) have recognized pain-reducing effects with somatic pain conditions and may be useful in FAP. To ensure treatment adherence, M.T. needs affirmation that antidepressant is not prescribed simply to treat depression. It is important that the clinician educate the patient on the role of antidepressants in the treatment of pain. Patient education resources such as diagrams help to show the physiologic basis for treatment of pain and describe descending inhibitory pathways.[117,148]

Gabapentin and pregabalin clinical trials have established their efficacy for neuropathic pain and fibromyalgia, but benefit for visceral or central pain syndromes is not established. NSAIDs offer little benefit because their action is located in the peripheral nervous system. Long-term treatment with benzodiazepines is not recommended because of the abuse potential and tendency to interact with other medications. For patients who are refractory to usual doses of antidepressant medication, referral to psychiatry should be made for treatment with atypical antipsychotic agents such as quetiapine.[117,148]

Risk of Addiction

CASE 55-7, QUESTION 3: There is concern about M.T.'s use of alcohol and escalating use of opioid medication. What is the risk that M.T. will become addicted to opioids?

Opioid use behaviors are stratified based on the risk of aberrant drug use. Aberrant drug use behaviors may occur along a spectrum from those less suggestive of addiction, such as an occasional, sanctioned increase in the opioid dose by a medical provider, to those that may be more suggestive of addiction, such as injecting oral formulations. Table 55-16 provides a list of risk factors for opioid misuse.[148,150] Important but less consistent risk factors include pain-related functional impairment such as sleep disturbance, mental health issues, history of child sexual abuse or neglect, and legal problems.[151,152] With respect to gender, women with chronic pain who report significant emotional issues were at increased risk for opioid misuse.[153]

M.T. has multiple behaviors in which some are more indicative of addiction such as concomitant alcohol use whereas others can be explained given the etiology of FAP. For example, high healthcare utilization for pain validation is common in patients with FAP. Also, aggressive complaining about the need for more opioid medication may be driven by M.T.'s perception that the current dose prescribed by her primary care physician no longer relieves her pain, implying tolerance has developed (Table 55-17).[149,154]

The factor that is most concerning for addiction is M.T.'s continued use of alcohol despite previous pancreatitis and misusing it to treat anxiety. There is also a risk of increased opioid side effects, especially sedation and respiratory depression, with concurrent use of alcohol. Multiple literature reports have confirmed there is a strong association between alcohol abuse and opioid addiction.[155,156] Guidelines for chronic opioid therapy strongly recommend clinicians conduct a risk assessment of substance abuse, misuse, or addiction before initiating opioid therapy.[50]

Table 55-16

Risk Factors for Opioid Addiction[149,150]

Concurrent abuse of alcohol or illicit drugs
Evidence of a deterioration in the ability to function at work, in the family, or socially that appears to be related to drug use
Injecting oral formulations
Multiple dose escalations or other nonadherence with therapy despite warnings
Obtaining prescription drugs from nonmedical sources
Prescription forgery
Repeated resistance to changes in therapy despite clear evidence of physical or psychological effects
Repeatedly seeking prescriptions from other physicians or emergency departments
Selling prescription drugs
Stealing or borrowing drugs from others

Table 55-17

Terms Related to Opioid Use[149,154]

Term	Definition
Misuse	Taking a prescription for a reason or at a dose or frequency other than for which it was prescribed.

	Use of a medication for a nonmedical use, or for reasons other than prescribed. For example, altering dosing or sharing medicines, which has harmful or potentially harmful consequences.
Abuse	Misuse with consequences involving the use of a substance to modify or control mood or state of mind in a manner that is illegal or harmful to oneself or others. Potentially harmful consequences include accidents, injuries, blackouts, legal problems, and sexual behavior that increases the risk of infectious diseases.
Addiction	A primary, chronic, neurobiologic disease with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.
Physical dependence	A state of adaptation manifested by a drug class–specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, or administration of an antagonist.
Pseudoaddiction	Condition characterized by behaviors that outwardly mimic addiction but are in fact driven by a desire for pain relief (e.g., constantly watching the clock to dose medication "on time" so pain does not become severe).[151]
Tolerance	A state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more opioid effects with time.

Assessment of Chronic Opioid Therapy

CASE 55-7, QUESTION 4: M.T. would like to continue with opioid therapy despite the concerns of her primary care physician. Is M.T. a candidate for chronic opioid therapy?

The Centers for Disease Control released new recommendations for opioid therapy that support the establishment of a treatment plan with the patient before starting opioid therapy that includes realistic goals for pain and function along with consideration of when therapy will be discontinued if benefits do not outweigh risks. Clinicians should continue opioid therapy only if there is clinically meaningful improvement in pain and function that outweighs risks to patient safety.[50] In the case of MT, a pain agreement (e.g., contract) should be established even if the goal is to eventually discontinue opioid therapy. There are multiple sources in the literature for information and guidelines on written agreements between the clinician and patient for chronic opioid therapy (COT).

The written COT agreement should include goals of therapy, how opioids will be prescribed and taken, expectations for follow-up and monitoring, alternatives to COT, expectations regarding use of concomitant therapies, and potential for tapering the regimen and discontinuing.[150] Indications for tapering and/or discontinuation of the opioid include failure to make progress toward therapeutic goals, intolerable adverse effects, or repeated or serious aberrant drug-related behaviors. Patient compliance requirements within the written agreement should include random urine drug screens for illicit substances or opioids obtained from other sources and limited prescribing (e.g., reduced quantities, biweekly prescribing) to help the patient manage use if necessary. In this case, M.T. has not made progress in meeting the goal of decreased emergency department utilization, she continues to use alcohol with her medication, and she has been resistant to trying other therapies despite the ineffectiveness of opioids in treating her pain. These behaviors would indicate M.T. is not a candidate for COT.

Screening tools that assess the potential risks for opioid misuse based on patient characteristics are helpful in determining eligibility for COT. Patient self-report questionnaires for assessing risk of aberrant drug-related behavior include the Screener and Opioid Assessment for Patients with Pain-Revised (SOAPP-R) and the Opioid Risk Tool (ORT).[150,154,157]

The Diagnosis, Intractability, Risk, Efficacy (DIRE) tool is a clinician evaluation instrument designed to assess the potential efficacy of chronic opioid therapy as well as harm.[158] In M.T.'s case, her DIRE score is 10, which would indicate she is not a suitable candidate for long-term opioid therapy. M.T.'s DIRE score and assessment are shown in Table 55-18.

Discontinuing Opioid Therapy

CASE 55-7, QUESTION 5: M.T. is going to be discontinued from opioids as part of the pain management plan. What methods are appropriate to safely discontinue opioid therapy in M.T.?

Guidelines strongly recommend that clinicians taper patients from chronic opioids if they have repeated aberrant drug-related behaviors, experience no progress toward meeting therapeutic goals, or experience intolerable adverse effects.[50,150] When tapering patients from long-term opioid therapy, the length of time the patient has been taking opioids needs to be considered. Approaches to opioid tapering range from a slow 10% dose reduction per week to a more rapid 25% reduction every few days. Evidence to guide specific recommendations on the rate of reduction is lacking, although the slower rate may help reduce the unpleasant symptoms of opioid withdrawal.[150,157]

There is insufficient evidence to guide recommendations for the use of short-acting versus long-acting oral opioids, or as-needed versus around-the-clock dosing during taper.[159] In this case, it is recommended that M.T.'s oxycodone dose be reduced slowly over 2 months in conjunction with starting psychological therapy for stress management and counseling for alcohol use. M.T. will need to be monitored for signs of withdrawal, which include anxiety, tachycardia, sweating, and other autonomic symptoms. Should withdrawal symptoms occur, they may be lessened by clonidine 0.1 to 0.2 mg orally twice a day.[160]

Table 55-18

DIRE Score for Patient M.T.

Score	Factor	Explanation
1	Diagnosis	1 = Benign chronic condition with minimal objective findings or no definite medical diagnosis (e.g., fibromyalgia, migraine headache, nonspecific back pain)
1	Intractability	1 = Few therapies have been tried, and the patient takes a passive role in his/her pain management process
7	Risk	(psychological + chemical health + reliability + social support)
	Psychological	2 = Personality or mental health interferes moderately (e.g., depression or anxiety disorder)
	Chemical Health	1 = Active or very recent use of illicit drugs, excessive alcohol, or prescription drug abuse
	Reliability	2 = Occasional difficulties with compliance, but generally reliable
	Social Support	2 = Reduction in some relationships and life roles
1	Efficacy Score	1 = Poor function or minimal pain relief despite moderate-to-high opioid doses
10	**Total** Score 7–13: not a suitable candidate for long-term opioid therapy Score 14–21: good candidate for long-term opioid therapy	

DIRE, Diagnosis, Intractability, Risk, and Efficacy score.

Cognitive Behavioral Therapies (CBT)

CASE 55-7, QUESTION 6: What nonpharmacologic therapies could be offered to M.T. to help with her pain management?

Psychological counseling and CBT are key components to successful management of the patient. The psychological approach to CBT has been shown to be beneficial in the treatment of FAP. CBT typically combines stress management, problem-solving, goal setting, pacing of activities, and assertiveness into a strategy for self-management of pain. Biofeedback, meditation, guided imagery, and hypnosis can all be incorporated within a CBT plan (Table 55-19). The objective is to help patients acquire a sense of hopefulness and resourcefulness, and develop positive coping skills.[161]

Complementary and alternative therapies such as spinal manipulation, massage, and acupuncture are commonly used in patients with chronic pain, but data supporting their use in FAPS are limited. Transcutaneous electrical nerve stimulation has been tried in FAPS patients, but the results are inconclusive.[148,161]

CANCER PAIN AND SYMPTOM MANAGEMENT

Pain is one of the most commonly experienced and feared symptoms of cancer. Cancer pain is defined as pain that results from treatment of the disease or the direct impact of tumor growth. During cancer treatment, 35% to 56% of patients will have pain with up to one-third of those patients having severe pain.[162,163] The type of cancer pain can be classified as somatic, neuropathic, or visceral. Approximately one-half of all cancer pain is somatic, arising from bone, muscle, ligament, subcutaneous tissue, or skin.[164]

Table 55-19

Cognitive Behavioral Therapy[161]

Meditation—intentional self-regulation of attention using a systematic focus on particular aspects of inner and outer body experience.
Biofeedback—self-regulatory technique that teaches a patient how to exert control over the physiologic processes exacerbating pain. Biofeedback equipment conveys physiologic responses as visual or auditory signals that the patient can observe on a computer monitor. With practice, the patient learns to control and change his/her physiologic responses by manipulating the auditory or visual signals.
Guided imagery—useful method to help patients with pain to relax and achieve a sense of control and distraction. This modality involves the generation of different mental images, evoked either by oneself or with help from the practitioner.
Hypnosis—a state of heightened awareness and focused concentration that can be used to manipulate the perception of pain.

Somatic pain is frequent with breast cancer, genitourinary tumors, bone metastasis, and lymphatic malignancies. Neuropathic pain may be caused by surgery, cancer chemotherapy, radiation, herpes zoster (shingles), and tumor progression such as advanced head and neck cancer. Visceral pain often presents with gastrointestinal cancers.[163,164]

Sixty-four percent of patients with advanced cancer report an increased frequency and intensity of pain compared with patients with early-stage cancer.[163] Factors influencing the degree of pain

---

include the primary cancer, stage of disease, location of metastasis, and comorbid medical conditions.[164,165] Each pain complaint must be assessed for time of onset, body location, pattern of progression, impairment of physical function, psychosocial impact, and other associated symptoms such as nausea, fatigue, shortness of breath, constipation, and mental status changes.

The initial treatment of cancer pain is based on the severity as reported by the patient. Factors to consider when starting an analgesic regimen include the pain etiology, patient tolerance (e.g., opioid doses), setting where the medication will be administered, and previous experience with analgesics that were efficacious or produced adverse effects. In general, mild pain (e.g., pain rated ≤4 out of 10 in severity) can be managed with nonopioid or a combination of nonopioid and a low dose of an opioid analgesic. Moderate-to-severe pain (e.g., pain rated >4 out of 10 in severity) usually requires a higher dose of an opioid analgesic. The treatment of neuropathic pain may require the use of anticonvulsant or antidepressant medication. Nerve blocks and invasive surgical procedures are options for pain control that is refractory to conventional medication management.[165]

Presentation and Treatment of Cancer Pain

CANCER PAIN ETIOLOGY

CASE 55-8

QUESTION 1: L.V. is a 58-year-old man who was diagnosed with stage IV squamous cell carcinoma of the subglottis 2 months ago. The cancer is locally advanced with involvement of multiple cervical lymph nodes. He had a modified neck resection to remove the primary tumor and lymph nodes while sparing the larynx. Chemoradiation therapy began 3 weeks after surgery with cisplatin 100 mg/m^2 every 3 weeks (days 1, 22, and 43) and external beam radiation delivering 70 Gy fractionated over the course of 7 weeks. L.V. is now in his fourth week of radiation therapy and continues to have significant neck and shoulder pain described as “sudden shock-like sensations with movement” and rated 6 out of 10 despite a recent increase in his oral ER morphine to 60 mg twice daily with immediate-release morphine 15 mg orally every 4 hours PRN for breakthrough pain. He also reports that his throat is getting so sore that he cannot bear to swallow and rates the pain 10 out of 10. L.V. appears quite fatigued and lethargic during his appointment with the radiation oncologist. The physical examination is remarkable for dry oral mucous membranes, erythema and mild ulceration of the oropharynx, and allodynia with light palpitation of the trapezius and sternocleidomastoid muscles with pain greater on the left side.

The radiation oncologist orders laboratory tests and the results are as follows:

General Chemistry:
Sodium, 132 mEq/L
Potassium, 4.2 mEq/L
Chloride, 101 mEq/L
CO_2, 26 mmol/L
Anion gap, 5 mEq/L
Glucose, random, 70 mg/dL
Urea nitrogen, 28 mg/dL
Creatinine, 1.5 mg/dL
Calcium, total, 9.0 mg/dL
CBC With Differential:
White blood cell count, 7.1 × 10^9/μL
Red blood cell count, 3.25 × 10^6/μL
Hemoglobin, 14 g/dL
Hematocrit, 43%
Mean cell volume, 91 × 10^6/μL
Mean cell hemoglobin, 30 pg/cell

Mean cell hemoglobin concentration, 33 g/dL

Platelet, 369 × $10^3/\mu L$

Absolute neutrophils, 5 × $10^9/L$

Absolute lymphocytes, 1.2 × $10^9/L$

Absolute monocytes, 0.2 × $10^9/L$

Absolute eosinophils, 0 × $10^9/L$

Absolute basophils, 0 × $10^9/L$

The radiation oncologist decides to admit L.V. to the hospital for dehydration and pain management. What are the possible etiologies of L.V.'s pain?

L.V. is presenting with a new complaint of a severe sore throat and persistent neck and shoulder pain. Laboratory data ruled out infection and myelosuppression. His kidney function may be impaired by dehydration and cisplatin therapy. The most likely causes of L.V.'s pain are the recent surgical neck resection and mucositis from external beam radiation.

L.V. also has postoperative peripheral neuropathy characterized by shock-like sensation in the neck and shoulders after the resection of the tumor. The physical examination of L.V.'s neck and shoulders is remarkable for allodynia, which can be present with neuropathy. The cervical lymph node resection may have caused neuropathy due to nerve damage via crushing, pressure, incision, or inflammation. This results in ectopic firing and changes in the receptive field causing nerve excitability and spontaneous activity (e.g., windup). Neuronal hyperexcitability may be related to overexpression of sodium channels and activation of the NMDA receptor.[166] Cervical plexopathy may also be contributing to the discomfort.

Mucositis occurs in up to 45% of individuals treated for head and neck cancer with the chemoradiation regimen L.V. is receiving.[167,168] Chemotherapy and radiation directly affect the proliferation of epithelial cells and connective tissue, causing damage to and loss of the mucosal barrier. On physical examination, the oropharynx is red and ulcerated, which is indicative of mucositis. Chapter 94, Adverse Effects of Chemotherapy and Targeted Agents provides information on the signs and symptoms of mucositis. Pain associated with mucositis is dependent on the degree of tissue damage, sensitization of nociceptors, and activation of inflammatory and pain mediators. L.V.'s complaint of sore throat pain limiting his ability to swallow is a common presentation of mucositis. In head and neck cancer patients treated with radiation, pain intensity scores directly correspond to mucositis and increase at week 3, often peak at week 5, and persist for weeks after the end of treatment.[166]

In addition, L.V. may have cisplatin-related neurotoxicity. Approximately 30% to 40% of patients may experience sensory loss as a result of direct neuronal DNA damage and apoptotic cell death caused by cisplatin. Neurotoxicity is a dose-limiting side effect for all the platinum agents. Cisplatin peripheral toxicity can occur in patients who receive a cumulative dose of more than 400 to 500 mg/m^2.[169] All sensory modalities are involved, but loss of large fiber function is often prominent. Persistent dysesthetic pain (i.e., an unpleasant abnormal sensation, whether spontaneous or evoked) is a late phenomenon that may continue to progress for several months after cessation of cisplatin.

CASE 55-8, QUESTION 2: L.V. was started on intravenous hydromorphone using patient-controlled analgesia (PCA) with an average usage of 14 mg/day. He now rates his pain as 4 out of 10. Owing to difficulty swallowing secondary to the mucositis and xerostomia, he had a gastric feeding tube placed for nutrition. The plan is to convert the intravenous hydromorphone to a transdermal fentanyl patch. What transdermal fentanyl patch dose should L.V. be started on, and what are the instructions for use?

TRANSDERMAL FENTANYL DOSE CALCULATION

Historically, the World Health Organization (WHO) analgesic ladder has been used to guide cancer pain management.[170] The downside to using this algorithm is that cancer pain rarely progresses in the stepwise fashion that the WHO ladder implies. Therefore, several organizations including the American Pain Society and National Comprehensive Cancer Network have proposed different strategies for managing cancer pain based on the assessment of the patient, development of an individualized care plan for pain, and symptom management.[42,165,171]

Before starting intravenous hydromorphone, L.V. has severe throat pain rated 10 out of 10 and moderate-to-severe neck and shoulder pain rated 6 out of 10. Because of the severity of pain and inability to swallow, intravenous opioid therapy using PCA is appropriate. Hydromorphone is a good choice for intravenous opioid therapy because it does not have active metabolites that could accumulate with renal insufficiency. The transdermal fentanyl patch is an excellent choice for L.V.'s eventual outpatient pain management because it will provide continuous release of opioid and is convenient to use.[172] Kadian, an extended-release morphine capsule, can be administered via a 16 French gastrostomy tube because the capsule can be opened and contents flushed through the feeding tube with water.[173] Limitations to the use of this formulation in L.V. include the need for patient manipulation of the gastric feeding tube with self-administration and the potential for morphine side effects secondary to metabolite accumulation if renal insufficiency persists.

Transdermal fentanyl patches are intended for opioid-tolerant patients with stable chronic pain. Opioid-tolerant patients are those who have been taking daily, for a week or longer, at least 60 mg of oral morphine, 30 mg of oral oxycodone, or at least 8 mg of oral hydromorphone or an equianalgesic dose of another opioid.[174] Respiratory depression associated with opioids is more likely to occur in opioid-naïve patients, patients with postoperative pain, and those with intermittent or mild pain that is managed with PRN opioid administration.[172,174] Before the current hospital admission, L.V. was taking 120 mg of ER morphine per day with additional oral immediate-release morphine for breakthrough pain; therefore, L.V. is a good candidate for a transdermal fentanyl patch.

L.V.'s transdermal fentanyl regimen will need to be determined by converting intravenous hydromorphone using an equianalgesic dose approximation. Doses of two different opioids (or two different routes of administration of the same opioid) are considered to be equianalgesic if they provide the same degree of pain relief. Table 55-20 provides equianalgesic opioid doses.[42,174] The calculations to convert L.V. from IV hydromorphone to transdermal fentanyl (Duragesic) are shown in Figure 55-7. There are several published tables for converting morphine to transdermal fentanyl that have been developed by researchers and manufacturers of transdermal fentanyl products. They provide slightly different dose conversion recommendations. Duragesic has wide morphine dose ranges, which may result in underdosing the transdermal fentanyl patch in cancer patients.[174,176] Breitbart et al. recommend a 2:1 ratio of oral morphine to transdermal fentanyl (i.e., 2 mg oral morphine/day is equivalent to 1 mcg/hour transdermal fentanyl), resulting in higher transdermal fentanyl doses, which may be excessive for elderly patients.[176] A study by Donner et al. suggested a dose ratio of 60 mg/day oral morphine is equal to 25 mcg/hour transdermal fentanyl, which falls between the manufacturer's table and the study recommendations by Breitbart et al.[176–178] The Donner conversion ratio is used in most references because it is less likely to cause underdosing or overdosing.[178]

Table 55-20

Equianalgesic Opioid Dosing[42,179]

	Equianalgesic Dose (mg)			
Opioid	**Oral (PO)**	**Parenteral (IV)**	**Duration (hours)**	**Comments**
Morphine	30	10	IM/IV/SC 3–4 hours	Standard for comparison of opioid analgesics.
			Oral short-acting 3–6 hours	Morphine not recommended in patients with severe renal impairment.
Hydromorphone (Dilaudid, Exalgo)	7.5	1.5	IM/IV/SC 3–4 hours	Exalgo (extended release) dosed every 24 hours.
			Oral short-acting 3–6 hours	Can be used in patients with renal or liver impairment.
Fentanyl[179]		0.05–0.1	IV/SC 1–2 hours	Refer to Figure 55-7 for transdermal fentanyl conversion example. Equianalgesic conversion ratios have not been established for transmucosal and transbuccal fentanyl formulations. Can be used in patients with renal or liver impairment.
Oxycodone	20		Oral short-acting	OxyContin (controlled release) is dosed every 8 or 12 hours.

			3–6 hours	Can be used in patients with renal impairment.
Buprenorphine (Buprenex, Butrans)[174,175]	0.3 (SL)	0.4		Available as sublingual tablets, sublingual film, transdermal patch, and injection. Suboxone (buprenorphine and naloxone) restricted to treatment of opioid dependence. Partial agonists not recommended for cancer pain management.
Meperidine (Demerol)[42,174]	300	100		Not recommended for routine clinical use by the American Pain Society.[42] Normeperidine is a toxic metabolite that produces anxiety, tremors, myoclonus, and generalized seizures.

SL, sublingual; SC, subcutaneous; PO, oral; IV, intravenous.

L.V.'s transdermal fentanyl patch dose is 116 mcg/hour (Fig. 55-7) using the dose ratio 60 mg/day oral morphine to 25 mcg/hour transdermal fentanyl. Because L.V.'s pain is well controlled based on the intensity rating of 4 out of 10, the dose of transdermal fentanyl should be rounded down to the nearest available patch size, which is 100 mcg/hour.[179] If L.V.'s pain was not controlled, the transdermal patch dose should be rounded up to the nearest available patch size.[174]

Patients who have been on opioid therapy for a prolonged time are likely to exhibit tolerance to the therapeutic effect. However, when switched to a different opioid, the level of tolerance may change (i.e., diminished tolerance to the new opioid) owing to the pharmacokinetic properties of the new opioid. This change in sensitivity to the new opioid is called incomplete cross-tolerance.[174] Most opioid doses need to be reduced by 25% to 50% after the conversion calculation to account for the incomplete cross tolerance.[42] The exception to this is methadone and fentanyl. Conversion ratios for methadone and fentanyl have already accounted for incomplete cross tolerance, so no further reductions are generally needed.[179] Therefore, L.V.'s transdermal fentanyl patch dose should not be reduced for incomplete cross-tolerance.

After the initial transdermal patch is applied, it will take 12 hours to reach the minimal effective blood concentration and up to 36 hours to achieve the maximal concentration. The transdermal fentanyl patch must be changed every 72 hours to maintain the steady-state blood concentration. Elderly, cachectic, or debilitated patients may have altered pharmacokinetics (i.e., more rapid rate of release) as a result of poor subcutaneous fat stores, thus requiring the transdermal fentanyl patch be changed every 48 hours.[176]

Step 1:
Determine the 24-hour total of the opioid that will be converted. For L.V., the 24-hour total of intravenous hydromorphone is 14 mg.

Step 2:
Select the equianalgesic dose ratio that corresponds to the opioid and route that will be converted from Table 55-20. Ratio calculations should be set up to correlate the actual dose with the equianalgesic equivalent as shown below:

$$\frac{\text{"X" mg total daily dose of new opioid}}{\text{mg total daily dose of current opioid}} = \frac{\text{equianalgesic factor of new opioid}}{\text{equianalgesic factor of current opioid}}$$

For conversion of L.V.'s hydromorphone dose, 1.5 mg intravenous hydromorphone is equianalgesic to 30 mg oral morphine:

$$\frac{\text{"X" mg total daily dose of new opioid}}{\text{14 mg intravenous hydromorphone}} = \frac{\text{30 mg oral morphine}}{\text{1.5 mg intravenous hydromorphone}}$$

Step 3:
Cross multiply the ratio to determine the total daily dose of oral morphine.

$(1.5)(X) = (14)(30)$
$1.5X = 420$
$X = 280$ mg of oral morphine

Step 4:
Determine L.V.'s transdermal fentanyl patch dose equivalent to 280 mg oral morphine using the conversion ratio of 60 mg/day oral morphine to 25 mcg/hour transdermal fentanyl will be used for the calculation.

$$\frac{\text{"X" mg total daily dose of new opioid}}{\text{280 mg oral morphine/ day}} = \frac{\text{25 mcg/ hour transdermal fentanyl}}{\text{60 mg oral morphine/ day}}$$

$(60)(X) = (280)(25)$
$X = 116$ mcg/hour transdermal fentanyl

Figure 55-7 Conversion of L.V. from intravenous hydromorphone to transdermal fentanyl.

L.V. should be instructed that the transdermal fentanyl patch should be applied to an intact, nonirritated and nonirradiated flat skin surface such as the chest, back, flank, or upper arm.[174] He should be warned about the risk of elevated body temperature (e.g., 40°C or 104°F) resulting in a faster release of fentanyl from the patch. The increased fentanyl level could cause serious respiratory depression. L.V. should be cautioned about avoiding external heating sources such as electric blankets, heating pads, tanning beds, sunbathing, hot baths, hot tubs, saunas, and heated water beds.[174] Fentanyl transdermal skin patches should not be used if damaged or cut because this may increase the absorption of the medication. L.V. should be told to wash his hands immediately if contact is made with the fentanyl gel that was inside the transdermal patch.

CASE 55-8, QUESTION 3: How should L.V. be transitioned from IV hydromorphone to the transdermal fentanyl patch?

TRANSITION TO TRANSDERMAL FENTANYL

Reducing the intravenous hydromorphone continuous infusion by 50% should occur 6 hours after the initial transdermal fentanyl patch is placed. Discontinuation of the IV hydromorphone continuous infusion and PCA dose should occur 12 hours after the initial transdermal fentanyl patch placement.[174] L.V. may need to use a short-acting (i.e., immediate-release) opioid until the maximal fentanyl blood concentration is achieved. Additional short-acting opioid may be needed for pain that occurs near the end of the 72-hour dose interval.

CASE 55-8, QUESTION 4: What are L.V.'s options for breakthrough pain management?

OPIOID THERAPY FOR BREAKTHROUGH PAIN MANAGEMENT

Breakthrough pain can be classified as spontaneous pain (i.e., frequently idiopathic, occurring with no known stimulus), incident pain (i.e., secondary to a stimulus that the patient may or may not be able to control), or end-of-dose failure (i.e., pain at the end of the dosing interval of the ER/LA opioid).[174] Incident pain can be reduced by instructing the patient to take a dose of short-acting opioid 30 minutes before activity. Spontaneous breakthrough pain should be treated by administering a short-acting opioid as soon as the pain is experienced. For patients on ER/LA opioid formulations experiencing end-of-dose failure, APS guidelines recommend supplementary doses of a short-acting opioid equivalent to 5% to 15% of the total daily dose to be taken every 2 hours as needed.[42] Short-acting opioid/acetaminophen products have a maximal dose to prevent liver toxicity with acetaminophen, thus creating a ceiling limit on the analgesic efficacy. Plain short-acting opioids (e.g., morphine, oxycodone, hydromorphone) should be used for patients requiring large doses for breakthrough pain.

In L.V.'s case, a short-acting opioid solution should be available for breakthrough pain before discontinuation of intravenous hydromorphone. The short-acting opioid can be administered in solution form through the gastric feeding tube or as oral tablets if L.V. can tolerate swallowing. L.V.'s oncologist would like to use oral morphine solution for breakthrough pain management. Because the transdermal fentanyl total daily dose is approximately equal to a total daily dose of 280 mg of oral morphine (Fig. 55-7), 10% of the total daily morphine dose would be 28 mg. The dose should be rounded to the nearest tablet size for a short-acting formulation, which is 30 mg, if L.V. would eventually take morphine tablets.

If more than two supplemental doses of short-acting morphine 30 mg are required daily to keep L.V.'s pain under control, an increase in the transdermal fentanyl patch dose should be considered. Moderate-to-severe pain may require an increase in the opioid total daily dose by 50% to 100%.[179]

Table 55-21

Equianalgesic Doses for Actiq (Transmucosal Fentanyl) and Fentora (Buccal Fentanyl)[180]

Current Actiq Dose (mcg)	Initial Fentora Dose (mcg)
200	100
400	100
600	200
800	200
1,200	400
1,600	400

Fentanyl administration by oral and intranasal transmucosal routes is approved for breakthrough pain management in cancer patients. The dose of both formulations is determined by titration (i.e., starting with the lowest dose and increasing based on pain relief) rather than a percentage of the total daily dose.[179,180] Equianalgesic doses of the transmucosal immediate-release fentanyl products are summarized in Table 55-21. The oral transmucosal route would not be preferred in L.V.'s case due to his dry oral mucous membranes secondary to radiation, which will impact absorption. Xerostomia is a common problem associated with radiation therapy of the head and neck and occurs in 80% of patients by week 7 of treatment. Problems related to xerostomia include difficulty speaking, chewing, swallowing, infections, mouth pain, and dental caries. Reports indicate up to 64% of patients may experience moderate-to-severe xerostomia 3 years after radiation treatment.[169,181] Chapter 94, Adverse Effects of Chemotherapy and Targeted Agents, provides information on topical treatment of mucositis and xerostomia.

CASE 55-8, QUESTION 5: L.V. has now completed chemoradiation therapy, and the mucositis pain has resolved. He continues to have persistent burning neuropathic pain rated 8 of 10 in the neck and shoulders and is using transdermal fentanyl 100 mcg/hour along with five doses of immediate-release oral morphine 30 mg/day. He is also taking gabapentin 900 mg orally 3 times a day and using a lidocaine 5% patch on each shoulder. L.V.'s oncologist wants to switch to oral methadone for neuropathic pain management. What oral methadone dose should L.V. be started on?

METHADONE DOSE CALCULATION

Methadone is an opioid agonist with analgesic activity at mu and delta receptors. Additional mechanisms of action that make it unique from other opioids and a good option for neuropathic pain include 5-HT and NE reuptake inhibition and antagonist effects at the NMDA receptor. Rotation to methadone is recommended when a patient has an inadequate response to other opioids or experiences intolerable side effects such as delirium, myoclonus, or nausea. A trial with methadone is warranted for L.V. because his neuropathic pain is not well controlled with transdermal fentanyl and other coanalgesics, including gabapentin and lidocaine. Refer to Case 55-4 for treatment of neuropathic pain.

Unlike short-acting opioids, methadone has a long half-life that ranges from 15 to 60 hours with a duration of action of 6 to 12 hours.[42] The conversion to methadone is not proportional like other opioid equianalgesic dose calculations. Older opioid dosing tables list a single conversion factor of 20 mg of oral methadone (or 10 mg IV methadone) equianalgesic to 30 mg of oral morphine. The single methadone conversion factor was intended for acute pain and does not account for chronic use. The conversion ratios vary with the morphine dose. Contemporary tables contain three or more morphine-to-methadone ratios to adjust for the magnitude of the methadone dose potency with higher morphine daily dose requirements for chronic noncancer and cancer pain. The most commonly used morphine-to-methadone conversions are provided in Table 55-22.[182]

Table 55-22

Morphine-to-Methadone Equianalgesic Dose Ratio[182]

Oral morphine dose (mg/day)	**<100**	**101–300**	**301–600**	**601–800**	**801–1000**	**≥1001**
Oral morphine-to-oral methadone ratio	3:1	5:1	10:1	12:1	15:1	20:1

L.V.'s total daily dose of morphine is 390 mg after converting transdermal fentanyl and adding the immediate-release morphine. Figure 55-8 provides the calculation to convert transdermal fentanyl to oral methadone in L.V. The dose of oral morphine falls within the dose range of 301 to 600 mg, which corresponds to a 10:1 oral morphine to oral methadone ratio (Table 55-22). L.V.'s total daily dose of methadone is approximately 39 mg (Figure 55-8). Guidelines recommend when switching to methadone from higher doses of another opioid, start methadone therapy no higher than 30 to 40 mg/day, with initial dose increases of no more than 10 mg/day every 5 to 7 days.[183] For most patients, the recommended methadone dose interval is every 8 hours. Older adults or frail patients may need methadone dosed every 12 hours to reduce the occurrence of side effects such as sedation.[42,174]

L.V.'s total daily dose of methadone should be divided into three doses and administered on an 8-hour interval. However, methadone is available in tablets (5 and 10 mg) or oral solution. The problem with L.V.'s total daily methadone dose is that it does not divide evenly using tablets. Splitting methadone tablets is not recommended because of the inconsistency in the dose with unequal tablet portions. Methadone solution is not convenient to use, and the dose needs to be drawn accurately with an oral syringe to prevent overdosing. L.V. would need approximately 11 to 13 mg of oral methadone solution per dose, which may be difficult to calibrate with the oral syringe. Therefore, L.V.’s methadone dose should be rounded down to the nearest available tablet size (e.g., 10 mg). Using a rapid switch transition from transdermal fentanyl to methadone, L.V. should be instructed to remove the transdermal fentanyl patch and begin methadone 10 mg orally every 8 hours approximately 12 hours after the patch has been removed. L.V. can continue to use morphine sulfate immediate-release 30 mg every 2 hours as needed for breakthrough pain. The immediate-release morphine dose may need to be reduced if L.V. has a good response to methadone.

Step 1:

Determine the 24-hour total of the opioid that will be converted. For L.V., the transdermal fentanyl 100 mcg/hour patch will need to be converted to oral morphine. In addition, L.V. is using 150 mg/day of immediate-release oral morphine.

The conversion ratio of 60 mg/day oral morphine to 25 mcg/hour transdermal fentanyl will be used for the calculation.

$$\frac{\text{"X" mg total daily dose of new opioid}}{\text{100 mcg/hour transdermal fentanyl}} = \frac{\text{60 mg/day oral morphine}}{\text{25 mcg/hour transdermal fentanyl}}$$

$(25)(X) = (100)(60)$
$X = 240$ mg oral morphine
Therefore, the total daily dose of oral morphine is 390 mg (240 mg + 150 mg)
The conversion ratio of $X = 200$ mg/day oral morphine

Step 2:

Select the equianalgesic dose ratio from the methadone table that corresponds to a total daily morphine use of 390 mg using the Donner method in step 1.[161,169]

According to the methadone dose Table 55-22, morphine doses in the range of 301–600 mg correspond to a 10:1 ratio (oral morphine to oral methadone).

$$\frac{\text{"X" mg total daily dose of new opioid}}{\text{390 mg total daily dose oral morphine}} = \frac{\text{1 mg oral methadone}}{\text{10 mg oral morphine}}$$

$(10)(X) = (390)(1)$
$10X = 390$
$X = 39$ mg of oral methadone/day
If the total daily dose of 340 mg oral morphine is used for the calculation, the total daily dose of methadone would be 34 mg.

Figure 55-8 Conversion of L.V. from transdermal fentanyl to oral methadone.

Because methadone has a long terminal half-life, it will take 4 or more days to achieve steady state. Unless L.V. is experiencing severe pain, the methadone dose should not be increased before 5 days. L.V. should be encouraged to use the immediate-release morphine during the transition period. The methadone dose can be adjusted based on the total daily dose of morphine used for pain control during the transition period.[174]

CASE 55-8, QUESTION 6: What are the signs and symptoms of methadone toxicity that should be communicated to L.V.?

METHADONE TOXICITY SIGNS AND SYMPTOMS

L.V. should be instructed to take methadone exactly as prescribed to prevent serious problems with breathing. He should be told about the signs and symptoms of methadone toxicity including shallow breathing, slowed respirations followed by periods of not breathing, slurred speech or difficulty talking, loud snoring, and inability to walk normally.[174] L.V. should be told to seek medical attention immediately if he experiences any of these signs and symptoms of methadone toxicity. He should also let family members living with him know about the risks of methadone so they can be aware of the signs and symptoms of methadone toxicity. Naloxone nasal spray and injection kits are now available for purchase at pharmacies to prevent fatal respiratory depression caused by opioids. L.V's family members should be counseled that this antidote would be beneficial to keep at home due to the risks associated with methadone.

CASE 55-8, QUESTION 7: What are the recommendations for monitoring cardiac toxicity associated with methadone use in L.V.?

METHADONE TOXICITY MONITORING

Methadone can cause prolongation of the QTc interval and increase the risk for development of torsades de pointes (potentially fatal arrhythmia). Factors associated with QTc prolongation are methadone doses greater than 100 mg/day, hypokalemia, low prothrombin level (suggestive of reduced liver function), and drug interactions involving the cytochrome P-450 3A4 enzyme.[183,184]

Consensus guidelines have been published on cardiac monitoring for patients taking methadone. The guidelines recommend pretreatment screening, electrocardiogram (ECG) evaluation, and risk stratification for QTc intervals exceeding 500 ms. For a QTc interval exceeding 500 ms, the consensus guidelines recommend reducing or discontinuing methadone (Table 55-23).[183,184] L.V. should have an ECG ordered prior to initiation of methadone to check his baseline cardiac function. Periodic ECG monitoring should be done if the dose is increased or L.V. experiences new symptoms such as dizziness or fainting which may signal a change in cardiac function.

CASE 55-8, QUESTION 8: How should opioid-related side effects be managed in L.V.?

OPIOID SIDE EFFECT MANAGEMENT

Appropriate use of opioids requires minimizing the occurrence of side effects including sedation, nausea, vomiting, pruritus, myoclonus, and cognitive impairment.[185] Table 55-24 provides information on the treatment of common opioid-related side effects.[185] In cancer patients, multiple factors may contribute to the emergence of opioid side effects such as renal insufficiency, nausea, and vomiting caused by changes in gut motility or chemotherapy, sedation owing to metabolic disturbances, and concomitant use of other sedatives or antiemetics. Tolerance to most of the opioid side effects develops in 3 to 7 days. If the side effects do not diminish with time, treatment may include switching to a different opioid or adding another medication to counteract the undesired effect.[42]

Respiratory depression is a serious adverse event and often is preceded by sedation. With methadone, the peak respiratory depressant effects typically occur later and persist longer than with other opioids. Naloxone is an opioid receptor antagonist that can be used to reverse respiratory depression caused by opioid medications. Opioid-tolerant patients are exquisitely sensitive to opioid antagonists. If naloxone is necessary, it should be titrated to effect to prevent profound withdrawal, seizures, arrhythmias, and severe pain (e.g., the analgesic effect of opioids is reversed with naloxone).[42] Patients who are overdosed on methadone will require a continuous IV infusion of naloxone for 24 to 36 hours because of the long elimination half-life of methadone.

Table 55-23

Consensus Recommendations for Methadone QTc Prolongation[183,184]

Inform patients of arrhythmia risk before prescribing methadone
Obtain patient history of structural heart disease, arrhythmia, and syncope
Obtain a pretreatment ECG before starting methadone and follow-up 30 days after starting methadone. Annual ECG is recommended. Additional ECG if the methadone dosage exceeds 100 mg/day or patient has unexplained syncope or seizures
Reduce or discontinue methadone if the QTc interval exceeds 500 milliseconds
Screen medication profile use of drugs that also may prolong or slow the elimination of methadone (i.e., SSRIs, antifungal agents, protease inhibitors, phenytoin, rifampin, phenobarbital, droperidol)

ECG, electrocardiogram; SSRIs, selective serotonin reuptake inhibitors.

Table 55-24

Pharmacologic Treatments for Opioid-Related Side Effects[185]

Side Effect	Treatment
Constipation	Stool softener, laxative, methylnaltrexone, oral naloxone, naloxegol
Sedation	Methylphenidate, modafinil
Pruritus	Diphenhydramine, hydroxyzine
Nausea	Prochlorperazine, haloperidol, metoclopramide, ondansetron, antihistamine
Dysphoria	Haloperidol, opioid rotation
Cognitive impairment	Methylphenidate, modafinil, opioid rotation
Myoclonus	Clonazepam, dose reduction, opioid rotation

CASE 55-8, QUESTION 9: What are other options for L.V. if his pain is not controlled with conventional pharmacotherapy?

REFRACTORY CANCER PAIN MANAGEMENT

Neuraxial opioid administration (epidural or intrathecal) can be used to treat cancer pain that is refractory to conventional therapy with opioids and coanalgesic medications. Long-term neuraxial therapy must be administered through an implantable intrathecal pump to avoid infection complications. Indications

---

for use of neuraxial therapy include neuropathic pain and mixed neuropathic–nociceptive pain. Medication selection is based on the patient's allergy history and response to a screening trial. Opioids (e.g., morphine, hydromorphone, fentanyl), local anesthetics (e.g., bupivacaine, ropivacaine), clonidine, ziconotide, and baclofen are commonly used in neuraxial regimens.

Complementary and alternative medicine therapies are widely used by patients in the management of cancer pain, dyspnea, and nausea and vomiting. Auricular acupuncture, therapeutic touch, and hypnosis may help with the management of cancer pain. Music therapy, massage, meditation, and hypnosis may help to reduce anxiety caused by dyspnea. Acupuncture and guided imagery may be beneficial in treating chemotherapy-induced nausea and vomiting.[185]

Oral cannabinoid formulations (dronabinol and nabilone) are approved by the FDA for chemotherapy-induced nausea and vomiting refractory to conventional antiemetic therapy.[186] Several studies of the endogenous cannabinoid receptors (CB_1 and CB_2) have demonstrated efficacy in the management of pain.[187] In the CNS, the CB_1 receptor is expressed in the areas involved in nociceptive processing, including the periaqueductal gray matter and dorsal horn of the spinal cord. The CB_2 receptor is expressed on cells of the immune system and is involved in modulation of inflammation and pain. CB_2 receptor activation has been shown to be analgesic in neuropathic pain models.[188,189] Medical use of cannabinoids has been debated in many states. In October 2009, the Department of Justice issued a memorandum to US Attorneys stating that federal resources should not be used to prosecute persons whose actions comply with their state's laws permitting medical use of cannabis. Currently, 23 states and Washington D.C. allow the use of medical cannabis for various diseases and including cancer pain.[190]

Care of the Critically Ill Adult

Matthew Hafermann, Philip Grgurich, and John Marshall

	CORE PRINCIPLES	CHAPTER CASES
	HOME MEDICATIONS IN THE INTENSIVE CARE UNIT	
1	Medications used to treat chronic conditions are often administered in the intensive care unit (ICU) as long as it does not provide harm to the patient. The decision to continue or hold medications that cause bleeding (e.g., warfarin, clopidogrel), have hemodynamic effects (e.g., blood pressure medication), have hypoglycemic effects (e.g., diabetes medications), and/or that can potentially interact with medications administered in the ICU is made on an individual basis based on risk and benefit.	**Case 56-1 (Question 1), Case 56-2 (Question 1)**
	PHARMACOKINETICS OVERVIEW AND DRUG SELECTION	
1	Available pharmacokinetic data are often determined in healthy subjects. Critically ill patients may have significant changes in all (ADME) pharmacokinetic parameters. The clinician should be attuned to those disease states most likely to induce alterations and to develop appropriate monitoring and management strategies for specific medications.	**Case 56-3 (Questions 1–8)**
	PAIN, AGITATION, AND DELERIUM	
1	Pain, agitation, and delirium commonly occur in critically ill patients for a variety of reasons. Clinicians should vigilantly assess patients for pain and provide adequate analgesia. They should attempt to identify and address underlying conditions leading to agitation and delirium.	**Case 56-4 (Questions 1, 2), Case 56-5 (Question 1), Case 56-6 (Question 1), Table 56-1**
2	Opioids are the most commonly used analgesics in the ICU. Patient-specific characteristics and differences between hydromorphone, fentanyl, and morphine should be considered when designing the optimal analgesic regimen for a patient.	**Case 56-4 (Question 3), Table 56-2**
3	Sedative agents may be utilized in some patients who remain agitated after reversible causes of agitation are thoroughly addressed. Propofol and dexmedetomidine are recommended first-line sedatives in most patients and should be titrated to achieve light sedation.	**Case 56-5 (Question 2), Table 56-3**
4	Clinicians can reduce the incidence of delirium by minimizing patients' exposure to risk factors for delirium and by implementing early mobilization protocols. Limited evidence suggests atypical antipsychotics	**Case 56-6 (Question 2)**

may help to treat delirium.	
STRESS ULCER PROPHYLAXIS IN THE INTENSIVE CARE UNIT	
① Stress-related mucosal damage can lead to occult gastrointestinal bleeding in high-risk critically ill patients. All ICU high-risk patients should be evaluated to determine the appropriateness of pharmacologic stress ulcer prophylaxis.	**Case 56-7 (Questions 1–3)**
GLYCEMIC CONTROL IN THE INTENSIVE CARE UNIT	
① Both hypoglycemia and hyperglycemia result in negative outcomes for critically ill patients. Generally, clinicians should target a blood glucose concentration of <180 mg/dL utilizing insulin to manage hyperglycemia.	**Case 56-8 (Question 1)**

HOME MEDICATIONS IN THE INTENSIVE CARE UNIT

The management of home medications in an intensive care unit (ICU) can be a very challenging aspect of care for the medical team. Medication reconciliation has become an increased priority for hospitals, and pharmacists play a vital role. One study found that 36% of patients admitted to the hospital had at least one medication error, and 85% originated from the patient's medication history.[1] Often the ideal method of obtaining a home medication list is through information obtained in a patient interview. However, this can be difficult in an ICU because of the fact that many patients are intubated, sedated, delirious, and/or unable to participate in a patient interview. Thus, other methods are required, including interviewing family or friends, calling retail pharmacies, locating outside medical records, or looking at previous hospital admissions. Medication reconciliation was shown to decrease discharge medication errors from 57% to 33% on a medical unit and from 80% to 47% on a surgical unit.[2] The importance of restarting home medications in the ICU varies among different agents and medication classes. Multiple types of adult ICUs exist in the United States, including medical, surgical, burn, and neurosurgical. This section will limit discussion to surgical and nonsurgical ICUs and the role of home medications for common situations in these ICUs.

ICU patients can be very complex by definition, and it can be difficult to ensure all important aspects of critical care are addressed daily. To enhance patient care and safety, the medical field has started to incorporate an effective tool borrowed from the airline industry: the checklist. One of the most widely used ICU checklists worldwide is FAST HUG, which stands for **F**eeding, **A**nalgesia, **S**edation, **T**hromboembolic prophylaxis, **H**ead of bed elevation, stress **U**lcer prophylaxis, and **G**lycemic control.[3] These are issues that should be addressed daily because of their impact on morbidity, mortality, and length of ICU stay. Clinical pharmacists working in an ICU have the option to use a personal checklist or other available checklists including a modified version of FAST HUG, FASTHUG-MAIDENS. This acronym stands for **F**eeding, **A**nalgesia, **S**edation, **T**hromboembolic prophylaxis, **H**ypoactive or Hyperactive delirium, **M**edication reconciliation, **A**ntibiotics, **I**ndications for medications, drug **D**osing, **E**lectrolytes, **N**o drug interactions, allergies, duplications, or side effects, and **S**top dates (of medications).[4] These are checklists that could be used in any ICU; however, each pharmacist needs to find what works best for them to ensure optimal medical care for their service and patients.

CASE 56-1

QUESTION 1: S.M. is a 62-year-old male who comes to the ICU with an upper GI bleed. He reports a 2-week history of poor oral intake and weight loss. For the last 2 days he has had several episodes of bloody stools and presented to his local clinic today with the following vitals: 90/51 mm Hg, HR 110 beats/minute, temperature 36.2°C. He is brought immediately to the ED where the following labs are obtained: Hct 17%, WBC 8.2 10^9/L, INR 5.2, Na 128 mEq/L, K 3.1 mEq/L, SCr 1.9 mg/dL. His current home medications are aspirin 81 mg daily, clopidogrel 75 mg daily, atorvastatin 40 mg daily, metoprolol XL 50 mg daily, lisinopril 10 mg daily, and warfarin 7.5 mg daily. The patient is immediately transfused with 2 units of red blood cells and is brought to the ICU. Which of his home medications should be held after he is admitted to the ICU?

Nonsurgical ICU Patients

For the nonsurgical ICU patient, the indication for admission is a major determinant in what medications can be restarted. Often Medical ICU patients come in with hemodynamic instability, reduced left ventricular ejection fraction, and/or alterations in renal or hepatic function, which significantly alter baseline pharmacokinetics. These patients must be evaluated on a case-by-case basis to determine if home medications should be restarted. Patients are admitted to the ICU because they need frequent monitoring and are in constant need of reevaluation. The medical team must consider that withdrawal can manifest from discontinuation of chronic home medications (e.g., β-blockers, baclofen) or from discontinuation of other illicit medications (e.g., heroin, cocaine, methamphetamine). Obtaining thorough patient history helps prevent withdrawal; however, because of the frequent inability to obtain a medical history the ICU team must determine if withdrawal treatment is appropriate based on vital signs and physical exam. This section will discuss home medications and how they should be addressed in common scenarios encountered in ICU patients.

Hemodynamic instability is one of the most common issues encountered in ICUs. Common causes of hypotension include hypovolemia, heart failure, and infection.

Knowing the patient’s baseline blood pressure can help determine the seriousness of the hypotension. A drop in baseline blood pressure can result in hypoperfusion and in the development of shock. If a patient cannot maintain adequate blood pressure, vasoactive medications (e.g., norepinephrine, epinephrine, phenylephrine, vasopressin) need to be initiated. Common indicators of lack of perfusion are monitored in the ICU, including cool skin, metabolic acidosis, change in mental status, elevated serum lactate levels, and reduced urine output. If a patient comes to the ICU with hypotension and signs of hypoperfusion, home blood pressure medications of all classes are held until there is a resolution of the underlying cause of the hypotension and hypoperfusion. Blood pressure medications should be slowly added back on at reduced doses to the hospital medication regimen.

Severe cases of hypertension in the ICU must be dealt with urgently to prevent stroke and/or end organ damage. Common causes of hypertension in the ICU are missed hemodialysis, medication noncompliance, volume overload, and pain. The differential of high blood pressure is extensive, so determining the cause of the elevated blood pressure will help determine the direction of treatment. Hypertensive emergencies, defined as a large elevation of SBP or DBP (>180 or >120 mm Hg, respectively), need to be treated immediately because of possible complications, including cerebral infarction, intracranial hemorrhage, aortic dissection, and renal failure.[5] Intravenous medications are often required to control blood pressure in the emergency room or during the early hours of ICU admission. Common medications used are nicardipine, diltiazem, diltiazem, hydralazine, esmolol, labetalol, and enalaprilat. These medications work immediately and can be titrated to lower blood pressures to desired targets. Intravenous medications are used in the short term until chronic antihypertensives can be administered and titrated. Restarting home blood pressure medications in the ICU is important unless there is a contraindication (i.e., new renal dysfunction) or the patient now has a new condition that warrants a change in medication class (i.e., β-blockers and ACEI for new heart failure). This topic is discussed further in Chapter 16, Hypertensive Crisis.

Since renal function is often unpredictable and unstable in the ICU, many classes of medications are withheld in the ICU. Renal function can change very quickly in the ICU and classic indicators of renal function such as SCr, which is used in creatinine clearance equations like Cockcroft and Gault and the Simplified

---

4-variable MDRD equation, are delayed in acute renal failure or falsely low in the elderly. For this reason, drugs that can be monitored using therapeutic drug monitoring (e.g., vancomycin) should be monitored frequently. Other indicators including urine output, blood pressure, and volume status should be factored into determining an appropriate dosing for medications that are eliminated through the kidney. All medications administered in the hospital setting should be monitored daily and adjusted based on renal function.

Diabetes medications can cause complications in the ICU. Metformin can cause a metabolic acidosis if given to patients with renal dysfunction and is withheld in most ICU patients. Sulfonylureas are also withheld because of the frequent changes in diet in the ICU, which can result in hypoglycemia. As a substitute to prevent hyperglycemia, most patients are converted to a short-acting sliding scale insulin regimen, which accounts for poor oral intake or the withholding of nutrition at certain points in an ICU stay. Sliding scale insulin regimens give varying doses of insulin based on a patient's most recent glucose level. Basal insulin can be considered for known diabetics, who are not receiving adequate control from sliding scale insulin.

Pain and medications used to treat pain are discussed in various chapters in this textbook (see Chapter 55, Pain and Its Management for more details). For a new ICU patient, knowing a patient's home medication pain regimen can be very helpful and often vital to good patient care. A patient on chronic opioids should be continued on a pain regimen, which includes opioids unless there is a contraindication to do so. Often the regimen must be modified to account for renal function and route of administration. For example, many of the long-acting medications cannot be crushed and put down a feeding tube, and a patient with renal dysfunction may need a lower dose or switch to an opioid that is not cleared through the kidney.

The dynamic nature of the ICU can make anticoagulation a very challenging issue in the ICU. Unless the patient will likely be in the ICU for a short period of time, vitamin K antagonists (e.g., warfarin) or the new oral anticoagulants (e.g., dabigatran, rivaroxaban, apixiban) will often be held in the ICU to prevent complications surrounding procedures and the altered pharmacokinetics in ICU patients. A detailed patient history is essential to determine the indication for anticoagulation. This will help the medical team determine if full anticoagulation should be continued. The discussion to continue anticoagulation will be determined on a case-by-case basis after weighing the risks and benefits of anticoagulation and often discussing the issue with consult services such as cardiology, vascular surgery, and the primary care provider. If full anticoagulation is required in the ICU, unfractionated heparin (UFH) may be the best option, because it can be stopped and reversed if needed. Almost all patients in the ICU are at increased risk for a venous thromboembolism (VTE) because of lack of mobility, elderly age (≥70 years), heart failure, respiratory failure, previous VTE, acute infection, obesity, and/or ongoing hormonal treatment. Because of increased risk for VTE, patients should be placed on anticoagulant thromboprophylaxis with low-molecular-weight heparin (LMWH), low-dose unfractionated heparin (LDUH) BID, LDUH TID, or fondaparinux unless a contraindication exists.[6]

One of the biggest complications for a pharmacist in an ICU patient is finding an ideal medication regimen for a patient who cannot take any medications by mouth or that have a feeding tube. For patients who have a feeding tube, medications can be given down the feeding tube in certain circumstances. The pharmacist must determine which home medications can be crushed or come in a solution or liquid form. Often long-acting medications must be converted to immediate release or the medication must be changed so it can be crushed to go down a feeding tube. The ISMP has created a resource for medications that cannot be crushed: http://www.ismp.org/tools/donotcrush.pdf. Certain patients in the ICU will be ordered to not receive anything by mouth including medications. It should always be clarified with the medical teams whether an NPO or "nothing by mouth" order includes medications. Many circumstances allow for the patient to receive oral medications on an NPO order. If medications cannot be given by mouth or there are concerns about absorption in the GI tract, the ICU teams will request that medications be converted from oral to intravenous form. While some medications have intravenous formulations, many do not. A clinical pharmacist can assist with dosage conversions, frequency of administration, and alternative options for medications that do not have intravenous equivalents.

Because of the fact that S.M. is actively bleeding, all anticoagulant and antiplatelet medications should be held. S.M. should have his aspirin, clopidogrel, and warfarin held. Additionally, because he has an elevated INR, he should receive vitamin K to reverse the effect of warfarin. Once his bleeding has stopped the team will have to determine which medications can be restarted and at what time the medications can be restarted.

Surgical Patients

CASE 56-2

QUESTION 1: D.H. is a 68-year-old with a PMH of CAD (drug-eluting stent placed 11 months ago), diabetes, and atrial fibrillation, who will be undergoing a knee replacement procedure in 1 week. His home medications on arrival to the hospital today include aspirin 81 mg daily, clopidogrel 75 mg daily, metoprolol XL 100 mg daily, and metformin 1,000 mg BID. All of his labs are within normal limits on the day of arrival. The surgery team wants your advice on what medications should be continued throughout surgery and what medications should be stopped.

Consequences of stopping a chronic medication before, or failing to restart that medication after surgery, can be significant. For example, abrupt discontinuation of a β-blocker during the perioperative period in a patient who has been on chronic β-blocker therapy can increase the risk of death in the intraoperative and postoperative period. The American College of Cardiology/American Heart Association (ACC/AHA) recommends continuation of β-blocker therapy in patients undergoing surgery who are receiving a β-blocker for treatment of conditions with ACC/AHA Class I guideline indications for the drugs (e.g., angina, symptomatic arrhythmia, post-myocardial infarction).[7] Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) increase the risk of hypotension after induction of anesthesia when these agents are not withheld 24 hours before surgery.[8] Stopping the ACEI before surgery, however, can result in adverse postoperative effects, such as rebound hypertension and atrial fibrillation. Therefore, the decision to continue or stop the ACEI or ARB before surgery is made on an individual basis, taking into consideration the indication for the ACEI or ARB and the type of surgery. Calcium-channel blockers, clonidine, amiodarone, digoxin, and statins should be continued. Preoperative withdrawal of a statin in a patient undergoing major vascular surgery, for example, increases the risk of myocardial infarction and cardiovascular death after surgery.[9] Diuretics are typically held the morning of surgery to minimize the risk of hypovolemia and electrolyte abnormalities.

Oral antidiabetic agents and noninsulin injectable agents are typically held the morning of surgery and not restarted until normal food intake resumes. In patients with renal dysfunction and those who may receive IV contrast media, metformin should

be discontinued 24 to 48 hours before surgery to reduce the risk of perioperative lactic acidosis. For patients on insulin therapy, a portion of the morning dose of intermediate- or long-acting insulin is generally administered on the day of surgery after a check of the patient’s blood glucose. Close blood glucose monitoring guides subsequent insulin doses to avoid hypoglycemia.[10]

Antiepileptics, antipsychotics, benzodiazepines, lithium, selective serotonin and norepinephrine reuptake inhibitors (SSRIs and SNRIs), tricyclic antidepressants (TCAs), and carbidopa/levodopa have a greater risk for withdrawal or disease decompensation than for perioperative complications. These medications should therefore be continued up to and including the morning of surgery.

Nonselective nonsteroidal anti-inflammatory drugs (NSAIDs) reversibly inhibit platelet aggregation and are often stopped 1 to 3 days before surgery, depending on the duration of action of the drug. Celecoxib does not affect platelet aggregation and may be continued up to and including the day of surgery. Nonselective NSAIDs and celecoxib should be held if there is a concern for impaired renal function during or after surgery.

For patients on anticoagulant or antiplatelet therapy, the risks for thromboembolism must be balanced with the risk for bleeding during and after the surgical procedure. For patients on warfarin, who are at high risk for perioperative thromboembolism, bridging anticoagulation therapy with IV heparin or LMWH before surgery is recommended. Warfarin may not need to be discontinued if the patient is undergoing minor surgery (e.g., certain ophthalmic, dental, or dermatologic procedures). For patients who have had coronary stents recently placed, discontinuing antiplatelet therapy prematurely can significantly increase the risk of perioperative stent thrombosis and have catastrophic consequences.[11] The 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery: Executive Summary recommends that patients undergoing urgent noncardiac surgery during the first 4 to 6 weeks after receiving a bare metal stent or drug-eluding stent implantation should continue dual antiplatelet therapy (aspirin plus P2Y12 platelet receptor-inhibitor) unless the relative risk of bleeding outweighs the benefit of the prevention of stent thrombosis. They also recommend that the management of perioperative antiplatelet therapy be determined by a consensus of the surgeon, anesthesiologist, cardiologist, and patient, who should weigh the relative risk of bleeding with those of prevention of stent thrombosis.[12]

Traditionally, it was thought that patients who have been taking long-term corticosteroid therapy before surgery will experience adrenal insufficiency in the perioperative period and should receive a supplemental stress-dose of hydrocortisone or methylprednisolone during and up to 2 to 3 days after surgery.[13] A recent review of the literature, however, found that patients on long-term corticosteroid therapy only require continuation of their normal daily dose of corticosteroid in the perioperative period. These patients are generally able to increase their endogenous adrenal function above their baseline corticosteroid dose to meet the increased demand from surgery; a supplemental stress dose of corticosteroid is not necessary. These patients can be closely monitored, and if hypotension develops, a stress dose of a corticosteroid should be administered at that time. Patients who have a known dysfunctional hypothalamic–pituitary–adrenal axis deficiency (e.g., Addison’s disease), on the other hand, will require supplemental corticosteroid doses in the perioperative period as they cannot increase endogenous cortisol production to meet the increased demand from surgery.[14]

Opioid-dependent chronic pain patients who undergo surgery often experience more severe acute pain after surgery. These patients should receive either their chronic opioid medication or a comparable dose of an IV opioid the morning of surgery to meet their daily requirements to avoid uncontrolled pain and opioid-withdrawal symptoms. The use of non-opioid analgesics or analgesic techniques (e.g., acetaminophen, peripheral nerve blockade, epidural analgesia) for perioperative analgesia should be maximized in a postoperative patient.[15] For D.H., since his stent is over 6 weeks old, his clopidogrel should be held 7 days prior to surgery. His warfarin should also be held 5 to 7 days prior to surgery and likely does not need bridging with a UFH or LWMH. His aspirin can be continued through surgery.

PHARMACOKINETIC ALTERATIONS IN THE ICU AND MANAGEMENT STRATEGIES

Pharmacokinetics in the Critically Ill

The dynamic nature of critical illness may cause drastic changes in the pharmacokinetic profile of many medications. Before describing these changes, it is important to first consider where the majority of available pharmacokinetic data is generated.

As a medication makes its way through the discovery process, pharmacokinetic data are obtained in phase I trials and in non-critically ill patients. Phase 1 trials in humans are most commonly done in healthy subjects in highly controlled environments. When pharmacokinetic data are obtained in phase II/III trials, critically ill patients are excluded. As a result, errors may arise in assuming that patients with the disease of interest, and more importantly, critically ill patients have similar pharmacokinetic parameters. While available pharmacokinetic data should always be consulted in formulating a therapeutic regimen, the pharmacist should be attuned to the limitations inherent in the data.

CASE 56-3

QUESTION 1: J.K. is a 67-year-old male who presents to the Intensive Care Unit (ICU) with a 3-day history of cough and shortness of breath. J.K. is diagnosed with severe sepsis due to pneumonia and is intubated on admission to the ICU. J.K. is started on broad spectrum IV antibiotics, including piperacillin–tazobactam and vancomycin. After receiving 6 L of lactated ringers, J.K. remains hypotensive, and a norepinephrine infusion is initiated to maintain his mean arterial pressure >65 mm Hg. J.K. is placed on enoxaparin 40 mg subcutaneously daily and pantoprazole intravenously for DVT and stress ulcer prophylaxis (SUP) respectively. On day 3 of his ICU course, J.K. develops acute kidney injury (AKI) secondary to sepsis/hypoperfusion with his serum creatinine rising from a baseline of 1.1 to 3.4 mg/dL. J.K. has an naso-gastric (NG) tube placed for enteral nutrition. On day 6 of his ICU stay, J.K. develops a severe Clostridium difficile colitis for which oral vancomycin is initiated.

What are potential abnormalities of medication absorption in J.K.?

With the exception of intravenous administration, all medications must undergo absorption in order to reach the systemic circulation. Bioavailability (F) is defined as the percentage of the administered dose that reaches the systemic circulation.

Gut function may be altered in J.K. for a variety of reasons including delayed gastric emptying, ischemic bowel, inflammation, and coadministration of interacting substances. Each of these issues may lead to significant delays and/or decreases in the amount of orally/enterally administered medication absorption.

Delayed gastric emptying is a common occurrence in the ICU patient population, occurring in 40% to 60% of patients.[16] It may be caused by many factors including postoperative ileus, trauma, head injury, sepsis, burns, or opioid use.[17] Delayed gastric emptying would be evident in J.K. if he was manifesting high gastric residual volumes or enteral feeding intolerance. Because most

---

medications are absorbed in the small intestine, delayed emptying would most likely affect the rate of absorption, slowing the onset of action of medications in J.K.

Ischemic bowel may also cause J.K. to have alterations in his ability to absorb oral/enteral medications depending on what portion and how much of the bowel is affected. In J.K., ischemic bowel may be caused by vasopressor use and/or the presence of a shock state. Because drug absorption occurs primarily in the small bowel, impaired blood flow to this area would be more likely to decrease the extent of absorption of medications.

Acute gut inflammation may increase the absorption of certain medications in J.K. With the development of severe clostridium colitis on day 6, J.K. may experience increased oral absorption of oral vancomycin. Under normal patient conditions, oral vancomycin is not orally absorbed because of the ionization and large size of the molecule. There have been several reports of therapeutic plasma levels of vancomycin being achieved with oral treatment of severe C. difficile infections.[18–21] The postulated mechanism is the severe inflammation in the colon allowing for the passage of larger, charged molecules into the bloodstream.

Oral medications are not the only route that may have altered absorption in the ICU. Subcutaneous absorption has also been shown to be remarkably altered in ICU patients, particularly those on vasoconstrictive (vasopressor) therapy. It is postulated that vasopressor treatment causes a decrease in subcutaneous tissue perfusion, resulting in impaired absorption of subcutaneously administered medications. Studies have shown that patients on LMWH therapy also receiving vasoconstrictive agents have markedly reduced peak and total anti-Xa activity when compared to other hospitalized patients.[22–24]

CASE 56-3, QUESTION 2: How should absorption issues in J.K. be managed?

Generally speaking, when there is a question of gut function in the intensive care unit, intravenous formulations are preferred when available. In cases where a given medication would produce an objective response (antihypertensive, hypoglycemic agents), enteral therapy may be attempted to assess patients' response. As above, the pharmacist should be attuned to the specific pharmacodynamic response of a given medication to assess therapeutic response with oral/enteral dosing.

In the case of J.K., consideration may be given to monitoring anti-factor Xa levels for enoxaparin, while he remains on vasopressor therapy. Trough levels of <0.1 IU/mL have been associated with increased risk of the development of DVT.[25] Additionally, if J.K. is deemed suitable for enteral medication therapy, his proton pump inhibitor therapy could be changed to a dissolvable (solu-tab) formulation, which generally is preferred to crushing and dissolving oral tablets to prevent obstructing tubes and for ease of administration. Consideration could also be given to monitor serum vancomycin concentrations more aggressively, because J.K. may be at risk for significant vancomycin absorption given his severe C. difficile infection while also receiving systemic vancomycin therapy.

CASE 56-3, QUESTION 3: What are the potential changes in the distribution of a medication in J.K.?

The distribution of a medication is defined briefly as where the drug goes once it is absorbed into the bloodstream. The extent of distribution of a medication is dependent on both physiochemical drug properties and patient-specific factors. The physiochemical properties of a drug that determine how extensively it distributes to tissues include lipophilicity and protein binding, with high lipophilicity leading to extensive tissue distribution, and lower protein binding contributing to more extensive distribution. Patient-specific factors that determine the distribution of a medication include weight, volume status, and vascular permeability.

J.K. has a multitude of factors that may affect the distribution of hydrophilic (low volume of distribution) medications. These include the presence of sepsis and large-volume crystalloid (normal saline) administration. These conditions result in decreased plasma concentrations of hydrophilic medications, leading to potentially subtherapeutic concentrations.[26]

Patients who have sepsis may possess several factors that would lead to a decreased plasma concentration of hydrophilic medications. These include the presence of capillary leak (third spacing), causing intravascular fluid to distribute to tissues, the administration of large volumes of intravenous crystalloid medications, and reduced tissue perfusion. This is particularly well-documented with antibiotic therapy in this patient population. Most infections occur in the interstitial fluid of tissues, thus interstitial antibiotic concentrations would be most relevant to determine efficacy. Studies have shown that the interstitial fluid concentration and subcutaneous concentration of antibiotics is 5 to 10 times lower and 1 to 5 times lower respectively, in septic patients as compared to normal controls.

Septic ICU patients may also have drastic changes in plasma protein (albumin) concentration because of reduced liver production and third spacing of albumin into tissue sites. Low plasma protein will cause an increase in the unbound fraction of drug, increasing distribution to tissues. Unfortunately, this increased distribution is more than offset by the increase in fluid concentration (secondary to capillary leak and volume administration) of the interstitial tissues, causing low concentrations of antibiotics in interstitial fluid.

Understanding that the distribution of hydrophilic antibiotics in J.K. (piperacillin/tazobactam, vancomycin) is likely increased in J.K., several strategies can be employed to offset these changes. Interventions include giving more frequent doses or continuous infusions with β-lactam therapy, and using large initial doses (30–40 mg/kg/day) of vancomycin in conjunction with targeting trough levels of 15 to 20 mg/L.[26]

CASE 56-3, QUESTION 4: What are the potential alterations in metabolism in J.K.?

Drug metabolism can occur in a variety of body tissues, including the kidneys, GI tract, lung, and liver. The liver is by far and away the predominant metabolizing organ and is the focus of this section. ICU patients may have alterations in hepatic enzyme activity, liver blood flow, and protein binding, all of which may influence the rate at which hepatically metabolized medications are biotransformed.

Liver metabolism is broken into two major categories, phase I and phase II metabolism, both of which transform drugs into more polar substances that are more readily excreted. Phase I metabolism refers to the cytochrome p450 enzyme system that works through oxidation, reduction, and hydrolysis. Phase II metabolism, in contrast, adds large polar molecules to the parent compound, including glucuronidation, sulfation, and acetylation.

There may be significant factors that alter phase I metabolism in J.K. These include kidney injury, inflammation, and hypothermia.

Renal dysfunction can reduce phase I metabolism through reduced hepatic cell uptake of medications and reduced biliary excretion.[27,28] The inflammatory response secondary to trauma has shown variable effects on enzymatic activity, with reduction in CYP 450 3A4, 2C19, and 2E1, with increased 2C9 activity.

Therapeutic hypothermia has been well-documented to reduce cytochrome activity across all isoenzyme families. This is especially well-documented with medications commonly given

to these patients, including neuromuscular blockers, fentanyl, phenytoin, and midazolam. It is important to consider that enzyme activity recovers during the rewarming process, necessitating close monitoring and potential dose adjustment.[29]

Hepatic blood flow (perfusion) may also be altered in J.K. Reductions in hepatic blood flow because of hypotension (shock) or shunting (cirrhosis) may have significant effects on prolonging the half-life of medications that are dependent on liver blood flow for metabolism. These medications are defined as having a high hepatic extraction ratio ($E > 0.7$) and would include medications such as midazolam and fentanyl.[17]

Protein-binding alterations may also occur in the critically ill and may subsequently affect the metabolism of select medications. Specifically, albumin concentrations may acutely decrease, thus increasing the free fraction of medications that are normally bound. This is especially relevant for medications that have high extraction ratios, as more medication would be available for removal, causing a net reduction in drug half-life.

CASE 56-3, QUESTION 5: How should metabolism issues be managed in J.K.?

To properly manage metabolism alterations in the ICU, the pharmacist should first be aware of the patient populations who are most likely to have altered metabolic rates/pathways. These include renal dysfunction, burns, therapeutic hypothermia, and decreased hepatic perfusion. In addition to identifying at-risk patients, the pharmacist should be aware of those medications that are most likely to have altered metabolism. These would include medications metabolized through the CYP 450 system as well as those with high extraction ratios ($E > 0.7$). Increased vigilance in monitoring for therapeutic effect/toxicity with these medications in at-risk patients is warranted.[17,29]

CASE 56-3, QUESTION 6: How is elimination altered in J.K.?

Elimination is the process by which a drug or its metabolites are removed from the body. While the kidney is the main organ that eliminates medications, it is important to remember that there are other organs (liver/lung) that also may contribute to elimination.[17] In addition, there exist several therapeutic interventions that occur in the ICU that also contribute to medication elimination, including continuous renal replacement therapy (CRRT) and extracorporeal membrane oxygenation (ECMO).[30]

Glomerular filtration is the primary method of renal clearance of medications, and renal drug removal is usually directly proportional to glomerular filtration rate (GFR). AKI is a common comorbidity in the ICU population, occurring in 1% to 25% of patients, leading directly to reduced medication elimination.[17] Other factors may increase the GFR in ICU patients, including trauma, burns, and use of vasopressors.

Renal function assessment is critical to appropriately dose adjusting renally eliminated medications and proves to be especially difficult in the ICU population. The serum creatinine measurement often lags behind actual GFR, because there exist changes in creatinine production and altered tubular secretion. In addition, most estimates of renal function, including the Cockcroft-Gault (CG) equation and the Modified Diet in Renal Disease (MDRD) equation, were validated only in patients with stable renal function.[31,32] Attempting to apply these equations to a patient with fluctuating serum creatinine measurements will result in inaccurate estimations of renal clearance.

In addition to renal function, there exist other modalities that contribute to drug elimination in specific ICU populations. These include CRRT and ECMO. While a detailed description of these processes is beyond the scope of this chapter, the clinician should remember that both may remove medications in clinically relevant quantities.

It is also important that the pharmacist consider not only the elimination of the parent compound but the presence active/toxic metabolites that require renal elimination. Examples of medications with clinically significant toxic metabolites are nitroprusside and meperidine.[33,34] Renal dysfunction may lead to accumulation of toxic metabolites, causing patient harm. Common medications given in the ICU with active metabolites are midazolam and diazepam. These active metabolites may accumulate in renal insufficiency and cause exaggerated/prolonged sedation/delirium.[35,36]

CASE 56-3, QUESTION 8: How should elimination alterations be managed in J.K.?

Estimation of renal function is critical to appropriately dosing many medications in the ICU. As above, using the usual process of calculating renal function is often inaccurate, and typical equations (CG/MDRD) should only be used in patients with stable creatinine values. In patients with unstable creatinine values, consideration should be given to calculating creatinine clearance using a 24-hour urine collection. Other data points should also be considered when determining an appropriate dose in critical illness and include urine output, trends in serum creatinine, and the specific medication to be dosed. For J.K., this would mean frequent monitoring of Vancomycin serum concentrations, anti-Xa monitoring for enoxaparin, and daily assessment of creatinine and urine output trends. Additionally, medications with active metabolites requiring renal elimination (midazolam) should be avoided if possible.

Pain, Agitation, and Delirium in the ICU

Pain, agitation, and delirium commonly occur in critically ill patients for a variety of reasons. Invasive interventions such as intubation and mechanical ventilation, acute and preexisting disease states, and surgery are just a few of the common causes of pain in critically ill patients.[37] Patients may become agitated and develop delirium because of untreated or inadequately treated pain or because of many other reasons, including drug abuse or withdrawal, adverse effects of medications, sleep deprivation, and the impact of comorbidities or severe illness.[37] Pain, agitation, and delirium are interrelated, and it is often difficult to differentiate these conditions based on symptoms in patients who are severely ill and often unable to communicate. They require prompt and effective interventions because they can lead to patient discomfort, heightened sympathomimetic activity, and negative patient outcomes. Clinicians should judiciously balance management of pain, agitation, and delirium in order to keep patients lucid, calm, interactive, free of pain, and cooperative with their care.[38]

CASE 56-4

QUESTION 1: J.A. is a 28-year-old male who presents to the emergency room after a severe motor vehicle accident. He presents with hemorrhagic shock, multiple rib and leg bone fractures, and a traumatic brain injury. He is immediately intubated and taken to the operating room for control of his bleeding and initial management of his fractures. His past medical history is significant for opioid abuse and bipolar disorder. After the operation, J.A. is transferred to the surgical ICU on mechanical ventilation with multiple chest tubes in place for management of injuries he sustained in the accident.

What causes of pain does J.A. have and what complications might they cause?

Table 56-1

Common Causes of Pain in Critically Ill Patients

Injuries and Diseases	**Interventions and Monitoring**	**Routine Care**
Trauma	Endotracheal intubation	Turning
Burns	Endotracheal tube for mechanical ventilation	Suctioning of respiratory secretions
Pancreatitis	Chest tube placement	Physical therapy
Necrotizing fasciitis	Wound care	
Decubitus ulcers	Surgery	
Immobility	Vascular access (arterial catheter)	
Preexisting disease states (e.g., cancer, chronic back pain)		

Up to 77% of patients discharged from ICUs report experiencing moderate or severe pain during their ICU stay.[39,40] This pain occurs during rest and with activity and is the most common memory patients have of their ICU stays.[41] Pain may occur because of injuries or diseases, therapeutic interventions, routine ICU care, or monitoring. Common causes of pain are listed in Table 56-1. Patients consistently report pain as the most traumatic memory from their ICU stay.[42] During the ICU stay, untreated pain can result in increased energy requirements, hyperglycemia, muscle breakdown, immunosuppression, increased risk of wound infection, decreased tissue perfusion, psychological distress, and impaired sleep. Long-term complications of untreated pain include chronic pain syndromes, neuropathy, posttraumatic stress disorder, and a decreased health-related quality of life.[37,43] In light of the acute and long-lasting consequences of pain as well as the prevalence of untreated pain in critically ill patients, it is important to diligently assess patients and utilize appropriate analgesics when indicated.

In J.A., potential causes of pain include trauma, postoperative pain, and the presence of an endotracheal tube and chest tubes. During his ICU stay, he may experience pain from routine care, including turning, suctioning of respiratory secretions, and eventually physical therapy.

CASE 56-4, QUESTION 2: How should J.A. be assessed for pain in the ICU?

Since patient-reported pain assessment is the optimal way to assess pain, whenever possible, clinicians should ask patients to rate their pain on a scale from 0 to 10 with 0 representing no pain and 10 representing the worst pain imaginable. For patients who cannot communicate with caregivers because of mechanical ventilation or other limitations, clinicians should assess patients' pain scores using validated nonverbal pain assessment tools that utilize patients' behaviors as indicators of pain. The two nonverbal pain assessment tools recommended in guidelines are called the Behavioral Pain Scale and the Critical-Care Pain Observation Tool.[37] The maximum score on each tool is 12 and 8, respectively, with higher values indicating more severe pain. Pain assessment should be protocolized such that it routinely occurs throughout each day of the patient's ICU stay. Clinicians should set the goal pain level and utilize analgesics as needed to achieve it while considering potential adverse effects. Generally, hemodynamic parameters such as blood pressure, heart rate, and respiratory rate should not be used to assess pain because they can be affected by other factors and do not correlate with self-reported pain; however, changes in vital signs may be used as a cue to further assess patients.[37]

CASE 56-4, QUESTION 3: How should clinicians manage pain in critically ill patients like J.A.?

Opioids, including fentanyl, hydromorphone, morphine, methadone, and remifentanyl, are the primary analgesics used in the critical care setting. Of these, fentanyl, hydromorphone, and morphine are used most commonly, whereas methadone is mainly used for long-term pain or pain that is refractory to other opioids. Because it is very short acting, very potent, and metabolized in the plasma, remifentanyl is most appropriate for pain that lasts only a short period of time in patients who are mechanically ventilated and in those with severe renal or hepatic dysfunction. Meperidine should not be used because it may cause seizures and other complications.[44] For treatment of acute pain, opioids should be given intravenously since enteral administration may be unreliable in critically ill patients because of incomplete absorption in patients with altered gastrointestinal motility and intramuscular absorption can be erratic.[37] In some cases, it may be impossible to completely alleviate pain because of dose-limiting side effects such as respiratory depression or altered mental status. In these cases, clinicians should attempt to make patients as comfortable as possible without inducing significant adverse effects.

The selection of a specific opioid relates to the pharmacokinetics and pharmacodynamics of the medications and depends on patient-specific characteristics as well as the nature of the pain the patient is experiencing. Table 56-2 lists key considerations for choosing between available opioids. When given as a single intravenous bolus injection, fentanyl has a faster onset and shorter duration of action compared to hydromorphone and morphine. This makes an intravenous injection of fentanyl most appropriate for pain that is short-lived such as procedural pain that might be associated with placement of a chest tube or intravenous catheter. In fact, procedural pain is best treated preemptively through administration of a bolus agent before the procedure.[37] The longer duration of action of hydromorphone and morphine makes these agents better when intravenous treatment of longer lasting pain is indicated. Alternatively, fentanyl, hydromorphone, and morphine may all be administered as continuous intravenous infusions in patients needing ongoing analgesia or those with severe pain.

All opioids can cause constipation, confusion, hallucinations, altered mental status, and respiratory depression when given in high doses. Clinicians should regularly monitor the bowel movements of patients receiving opioid analgesia and a bowel regimen containing both a stimulant laxative and a stool softener should be administered, if indicated. Opioids may all cause a decrease in blood pressure if the patient's blood pressure is increased because of pain and in patients who are hypovolemic. Importantly, morphine is the only opioid that causes histamine release, which can lead to flushing, bronchospasm, and hypotension. These complications underlie the recommendation to avoid morphine in patients who are hemodynamically unstable, at risk for hypotension, or those with bronchospasm. Morphine has an active metabolite that is cleared by the kidneys, while fentanyl and hydromorphone are metabolized in the liver to inactive metabolites. Thus, hydromorphone and fentanyl are preferred over morphine in patients with renal failure. Another unique side effect relates to QTc prolongation resulting from methadone. Because QTc prolongation can potentially cause cardiac arrest, electrocardiograms should be regularly monitored in patients receiving methadone, especially in patients concurrently receiving other QTc-prolonging agents. Serum concentrations of magnesium and potassium should be monitored, and these electrolytes should be repleted, as needed, to minimize arrhythmias. Because fentanyl is the most lipophilic of the three most commonly used opioid analgesics, prolonged administration via intravenous infusion may lead formation of a depot in adipose tissue. After cessation of the fentanyl infusion, drug may distribute from the fat into the bloodstream and prolong the effects of drug.

Table 56-2

Selected Characteristics of Opioids Used in Critically Ill Patients

	Onset	Duration (IV Bolus Dose)	Active Metabolite	Adverse effects & Other Considerations	Equipotent IV Dose (mg)
Morphine	5–10 minutes	2–4 hours	Yes (cleared renally)	Histamine release (hypotension, bronchospasm, flushing)	10
Hydromorphone	5–15 minutes	2–4 hours	No		1.5
Fentanyl	1–2 minutes	30–60 minutes	No	Accumulates in adipose tissue with prolonged infusion	0.1

In addition to opioids, clinicians may consider adjunctive analgesics in selected patients. For example, nonsteroidal anti-inflammatory agents and acetaminophen may be considered to minimize overall opioid requirements and potentially reduce opioid-related complications. For patients experiencing neuropathic pain, enterally administered gabapentin and carbamazepine can be helpful. Finally, for patients with rib fractures or those who have undergone thoracic or abdominal surgery, thoracic epidural analgesia results in better pain control as compared to opioid monotherapy.[37]

Because J.A. is likely to experience ongoing pain as a result of his trauma, multiple fractures, and surgery, he should be initiated on opioid analgesia. If he remains hypotensive, at risk for hemodynamic compromise, or is in renal failure, morphine should be avoided. Some centers would routinely use fentanyl or hydromorphone in most patients to minimize hemodynamic complications. It would be most appropriate to administer fentanyl as a continuous infusion, while hydromorphone could be given continuously or as repeated intravenous boluses. Because of his rib fractures, J.A. could also be considered for thoracic epidural analgesia with an opioid.

CASE 56-5

QUESTION 1: During his stay in the surgical ICU, J.A. begins to exhibit signs of agitation including diaphoresis, tachycardia, pulling at his endotracheal tube, and even trying to strike his caregivers.

What are some causes of agitation that J.A. might be experiencing and how should he be initially treated?

Agitation is very common in critically ill patients and can lead to adverse consequences arising from sympathomimetic effects.[45] Patient care can be complicated if agitation leads to patient removal of devices, such as endotracheal tubes or intravenous lines, necessary for their care. Patients may exhibit symptoms of agitation for a variety of reasons including pain, delirium, hypoxemia, hypoglycemia, hypotension, or withdrawal from alcohol and other drugs. Given the ubiquity of pain in critically ill patients and the difficulty in assessing patients who cannot communicate, clinicians should always consider pain as a potential cause of agitation and administer analgesics when they suspect pain. In fact, current guidelines recommend analgesia-first sedation strategies that emphasize aggressive use of analgesics before administration of sedative agents.[37] Other general strategies to treat anxiety and agitation in critically ill patients include keeping patients as comfortable as possible, reorienting patients if they misperceive their surroundings or situations, promoting a normal sleep–wake cycle by helping patients to stay awake during the day and minimizing barriers to sleep overnight. Whenever possible, clinicians should attempt to identify and treat the underlying cause of agitation before initiating a sedative agent. For instance, if an agitated patient is found to be hypoglycemic, the hypoglycemia should be corrected, and the patient should be reevaluated before starting a sedative. By identifying and addressing the cause of agitation, clinicians can avoid complications associated with sedative medications, such as over-sedation and delirium.[37]

Clinicians should assess critically ill patients who are agitated using a validated sedation assessment tool.[37] The two most rigorously evaluated tools are the Richmond Agitation-Sedation Scale (RASS) and the Sedation-Agitation Scale (SAS). Both tools effectively discriminate different levels of sedation, have high inter-rater reliability, and have been show to correlate reasonably well with objective measures of brain function.[46–48] Scores on the RASS range from –5 to +4 while the SAS varies from 1 to 7. The lowest numbers of the scales indicate a patient is unarousable, while the highest numbers on the RASS and SAS correspond to combativeness and dangerous agitation, respectively. By quantifying patients' level of sedation using one of these tools, multidisciplinary caregivers can determine the desired level of consciousness and appropriately administer medications to target this level of consciousness while avoiding excessive sedation. Generally, sedatives should be titrated to achieve light levels of sedation, which correspond to RASS scores of –1 to 0 and SAS scores of 3 to 4.[37] Maintaining patients at light levels of sedation instead of deeper levels of sedation, in which they are more difficult to arouse and are less interactive, has been shown to reduce duration of mechanical ventilation and ICU length of stay.[49,50] Sometimes, patients' clinical conditions may necessitate deeper levels of sedation. Some clinical situations in which deeper sedation may be appropriate include active severe alcohol withdrawal, refractory status epilepticus, intracranial hypertension, ventilator dysynchrony, severe lung injury, or paralysis with neuromuscular receptor blocking agents.

J.A. may be agitated because of pain from his traumatic injuries as well as metabolic disturbances or other causes. His level of consciousness should be evaluated using the RASS or SAS. Since he is intubated, J.A. should be assessed for pain using a validated nonverbal pain assessment tool, and his pain should be treated if indicated. His vital signs should be evaluated to identify hypotension or hypoxia, and his blood glucose concentration should be measured. Abnormalities in these values should be corrected as needed. Clinicians should review J.A.'s past medical history, social history, and home medication list to identify any potential that he might be experiencing withdrawal from alcohol, illicit substances, or prescribed medications that he was taking before hospital admission such as benzodiazepines or opioids. If he is unaware of his surroundings or current condition, J.A. should be reoriented. His sleep pattern should be addressed. Finally, the patient's current medication list should be reviewed for medications, such as steroids and anticholinergic drugs, that might cause behavioral changes and these medications should be discontinued if identified. Only after thoroughly assessing the patient for potentially reversible causes of agitation, should the health care team consider initiating a sedative medication with the goal of achieving a light level of sedation in J.A.

CASE 56-5, QUESTION 2: If J.A. requires sedation, which medication would be preferred?

Several agents, including propofol, dexmedetomidine, and benzodiazepines, can be used to treat agitation in critically ill patients. No particular sedative is best for all patients. Although benzodiazepines have been widely used over time, recent guidelines suggest that propofol and dexmedetomidine are preferred in most patients because they may result in decreased ICU length of stay and duration of mechanical ventilation as compared to benzodiazepines.[37,51–53] Decisions about the optimal sedative agent for individual patients depend on the reason for sedation and sedation goals, expected duration of sedation, pharmacology of the medication in the specific patient, and cost-effectiveness.[37] A summary of key clinical considerations relative to commonly used sedatives is provided in Table 56-3.

Propofol is a highly lipophilic sedative that binds to multiple receptors and exerts sedative, hypnotic, anxiolytic, antiemetic, and anticonvulsant properties.[37] Because of its high lipophilicity and formulation in a 10% lipid emulsion, propofol readily crosses the blood–brain barrier and demonstrates a rapid onset of effect and quick offset after short-term use. However, patient awakening after prolonged use can be variable because of its deposition in adipose tissues.[54] Propofol can be rapidly titrated in order to achieve the desired level of sedation. It is suited for regular awakenings that are required for neurologic examinations in patients with brain injuries, and it facilitates daily awakening as part of sedative and ventilator weaning protocols.[53,55] Adverse effects of propofol include respiratory depression, hypotension resulting from vasodilation, bradycardia, hypertriglyceridemia, pancreatitis, myoclonus, and green or white discoloration of the urine.[56,57] Because of the dose-dependent suppression of respiratory drive, continuous infusions of propofol should only be administered to patients who are mechanically ventilated. Patients should be regularly monitored for hypertriglyceridemia when receiving propofol over the course of several days and the drug should be stopped or weaned if significant hypertriglyceridemia develops. Patients with allergies to eggs, soybeans, and sulfites may experience allergic reactions because of components of the lipid emulsion and some generic formulations.[58] In order to reduce burning and stinging associated with administration, propofol should be administered through large-bore intravenous lines whenever possible. Although propofol is formulated with a preservative to prevent bacterial growth, product labeling suggests the bottles and tubing should be changed every 12 hours, and line integrity should be assessed to prevent bacterial contamination. The caloric load of the lipid vehicle should be considered when evaluating nutritional needs in patients receiving propofol.

Propofol may cause a life-threatening syndrome called propofol infusion syndrome (PRIS) in about 1% of patients. PRIS is characterized by metabolic acidosis, hypertriglyceridemia, progressive hypotension, bradyarrythmias, and cardiovascular collapse. Other complications of PRIS may include AKI, hyperkalemia, rhabdomyolysis, and liver failure.[59,60] PRIS has been observed most commonly at doses exceeding 70 mcg/kg/minute and with use beyond 48 hours, but it has been reported at lower infusion rates and with shorter infusions.[61,62] Because PRIS can be difficult to distinguish from other conditions in critically ill patients and because of its high mortality rate, members of the health care team should diligently monitor patients in order to rapidly identify PRIS. When PRIS is suspected, propofol should be discontinued and patients should receive appropriate supportive care.[37]

Dexmedetomidine is a centrally acting α-receptor agonist that is similar to clonidine. It demonstrates greater anxiolytic and fewer symptholytic properties as compared to clonidine. In addition to anxiolysis, dexmedtomidine also has sedative and opioid-sparing effects. It does not have anticonvulsive characteristics, induce amnesia, or cause respiratory depression.[37] Dexmedetomidine often allows patients to awaken more easily and better interact with caregivers as compared to propofol and benzodiazepines, but it is not appropriate for patients requiring deeper levels of sedation and those paralyzed with neuromuscular receptor antagonists.[63] Dexmedetomidine starts working within approximately 15 minutes after the initiation of an infusion and reaches its peak effect at 1 hour.[64,65] Clinicians may administer a bolus to achieve faster onset, but bolus administration is associated with increased risk of hemodynamic instability, which can manifest as either hypertension or hypotension and bradycardia.[66] Additional adverse effects include nausea, atrial fibrillation, and, rarely, cardiogenic shock.[67] In the United States, dexmedetomidine is approved for use as a continuous infusion at doses up to 0.7 mcg/kg/hour for a maximum of 24 hours, but clinical trials have demonstrated safety and effectiveness at doses up to 1.5 mcg/kg/hour for as much as 28 days.[68–70] Doses may be titrated every 30 minutes. Patients with severe hepatic disease may require lower doses of dexmedetomidine to avoid prolonged offset of effect and excessive hemodynamic effects. Dexmedetomidine-induced hypotension and bradycardia may occur more commonly in patients who are hypovolemic or those who have cardiovascular instability.[71] Importantly, because dexmedetomidine does not cause respiratory depression, it can be continued during and after extubation, unlike propofol.[71,72] When continuing dexmedetomidine in this fashion, clinicians should be aware that it may cause loss of oropharyngeal muscle tone, resulting in airway obstruction. Consequently, patients getting dexmedetomidine without mechanical ventilation must receive continuous respiratory monitoring.

Table 56-3

Clinical Considerations with Sedative Agents

	Receptor Binding Site	Onset (minutes)	Effect of Renal Failure	Effect of Hepatic Failure
Midazolam	$GABA_A$	2–5	Effect prolonged (accumulation of parent drug and active metabolite)	Effect prolonged
Lorazepam	$GABA_A$	15–20	Accumulation of propylene glycol	Effect prolonged
Propofol		1–2	No clinically significant	No clinically significant

	GABA$_A$, nicotinic, glycine, muscarinic		effect	effect
Dexmedetomidine	Central α-2	5–10	No clinically significant effect	Effect may be prolonged in severe hepatic failure

---

Benzodiazepines are GABA receptor agonists that demonstrate anxiolytic, sedative, hypnotic, and anticonvulsant effects.[73] Current guidelines no longer recommend use of benzodiazepines as first-line sedatives in most critically ill patients, although they remain the mainstay of therapy for management of alcohol withdrawal.[37] Benzodiazepines can potentiate respiratory failure and hypotension, especially when coadministered with opioids.[35] They can also cause mental status changes and are risk factors for development of delirium.[70,74,75] Patients may occasionally experience a paradoxical reaction involving agitation and restlessness. Elderly patients are more likely to experience adverse effects, while patients taking benzodiazepines prior to hospitalization and those on them for long periods of time may demonstrate decreased sensitivity. Usually, benzodiazepines are administered parenterally in the critical care setting and the most commonly used agents are lorazepam and midazolam. Either lorazepam or midazolam may be given via intermittent or by continuous intravenous infusion, but the two drugs have key differences relative to their pharmacokinetic, pharmacodynamic, and adverse effect profiles. Because it is more lipophilic, midazolam has a faster onset and shorter duration of action than lorazepam. However, because midazolam deposits in the adipose tissue, it can lead to variable and prolonged awakening when it is administered continuously over the course of several days.[76] Midazolam undergoes hepatic metabolism to an active metabolite, which is eliminated renally, while lorazepam is inactivated in the liver. Both agents should be used cautiously in renal and hepatic dysfunction because end organ impairment prolongs the elimination half-life of both drugs. Lorazepam is formulated in a propylene glycol vehicle, which can accumulate at doses as low as 1 mg/kg/day and cause metabolic acidosis and AKI.[77,78] When benzodiazepines must be used clinicians should carefully manage the dosing regimen to target the desired level of sedation at the lowest dose possible. Avoiding continuous infusions of benzodiazepines in favor of as needed bolus doses based on symptoms of agitation may result in decreased total benzodiazepine exposure and a lower chance of benzodiazepine-related complications.

After thoroughly assessing J.A. and addressing reversible causes of agitation such as metabolic disorders and withdrawal syndromes, sedation with propofol should be considered if he remains agitated and his hemodynamics are adequate. Propofol and dexmedetomidine are both suggested first-line sedatives according to current guidelines. However, because J.A. may require frequent awakenings for neurologic examinations, the faster offset of effect with propofol may make it more appropriate. J.A.'s blood pressure and heart rate should be monitored when propofol is started, and it should be titrated to a light level of sedation based on the RASS or SAS. His triglyceride concentrations should be evaluated periodically if propofol is administered for several days, and clinicians should be aware of the symptoms of PRIS in order to identify any potential episodes as soon as possible.

CASE 56-6

QUESTION 1: After receiving care in the ICU and remaining intubated and lightly sedated for several days, J.A.'s sedation is lightened, but he does not seem to be himself. He alternates between unresponsiveness and agitation. He is unable to tell caregivers where he is or answer simple questions. Could J.A. be experiencing delirium?

Delirium is a symptom of acute brain dysfunction that involves the following combination of symptoms: acute change or fluctuation from baseline mental status, inattention, and disorganized thinking or altered level of consciousness.[79,80] Patients who are delirious may experience hallucinations, delusions, or hyperactivity, but these symptoms are not present in all delirious patients. In fact, three different forms of delirium have been described based on the symptoms that patients demonstrate. In hyperactive delirium, patients are agitated, while in hypoactive delirium they are calm or lethargic. Patients with mixed delirium fluctuate between these two subtypes.[37]

Delirium occurs at least once during the ICU stay in up to 80% of critically ill patients and is associated with negative patient outcomes, including increased mortality, ICU and hospital-length of stay, long-term cognitive impairment, and health care costs.[81–84] Clinicians are more likely to fail to identify delirium if patients manifest hypoactive delirium rather than hyperactive delirium.[85] In order to identify patients who have delirium, current guidelines recommend that clinicians routinely assess patients several times each day using a validated delirium assessment tool.[37] The two recommended tools for assessing delirium are called the Confusion Assessment Method for the ICU (CAM-ICU) and the Intensive Care Delirium Screening Checklist (ICDSC).

Based on his symptoms, J.A. is likely experiencing delirium. It is clear that his mental status has changed from baseline as "he does not seem to be himself." In addition, the fluctuation between unresponsiveness and agitation combined with the inattention and disorganized thinking he is exhibiting by not being able to answer simple questions fulfill the other criteria of delirium. Clinicians should formally evaluate J.A. for delirium using a validated tool such as the CAM-ICU or the ICDSC.

CASE 56-6, QUESTION 2: How should clinicians work to prevent and treat delirium in critically ill patients like J.A.?

There are a variety of modifiable and non-modifiable risk factors associated with the development of delirium in critically ill patients.[37] Non-modifiable risk factors include baseline dementia, hypertension, alcoholism, and greater severity of illness.[37,75,86] Current evidence suggests that benzodiazepine exposure, very deep sedation, and anticholinergic medications may increase the risk that patients develop delirium. Any association between opioids and propofol and delirium is unclear because of conflicting and limited evidence, respectively.[37]

Evidence suggests delirium may be prevented with early mobilization protocols, in which nurses, physical therapists, and other clinicians assist critically ill patients in getting out of bed and ambulating. Studies of these protocols have demonstrated that they are safe and associated with significant reductions in

---

delirium, hospital and ICU length of stay, and duration of mechanical ventilation when used in critically ill patients.[87,88] No pharmacologic therapy has been shown to prevent delirium in heterogeneous groups of critically ill patients.[37]

Although haloperidol has been used historically to treat delirium in critically ill patients, there is an absence of high-quality published literature in broad groups of critically ill patients. Consequently, current guidelines make no recommendations regarding the use of haloperidol for treatment of delirium. Atypical antipsychotics may be considered to help reduce the duration of delirium; however, published literature supporting their use is very limited.[37,89] Evidence suggests that using dexmedetomidine instead of a benzodiazepine for management of agitation may result in less delirium.[68,70,90]

Delirium can be prevented in patients like J.A. through the use of early mobilization protocols and minimizing risk factors for delirium such as benzodiazepines. No pharmacologic strategy has been convincingly demonstrated to reduce delirium, although evidence suggests that atypical antipsychotics might have some role and could be considered.

Stress Ulcer Prophylaxis in the ICU

The development of stress ulcers in critically ill patients is a common complication of ICU patients. Stress ulcers from critical illness began to be recognized in the 1960s when one study found that 8/150 (5%) of consecutive ICU patients were found to have massive bleeding resulting from stress ulcers.[91] Stress ulcers usually develop in the mucosal layer of the stomach after high stress events and can result in ulceration and progress to clinically significant bleeding.[92] Up to 15% of patients in the ICU will develop an overt gastrointestinal (GI) bleed if not given SUP, which makes it a preventable complication of critical illness.[93] Despite there being a large volume of research in this area, there lacks a consensus on the management and prevention of stress ulcers.

Patients with serious illness or trauma can develop stress ulceration within hours of the inciting event. There are various degrees of stress ulceration and they can develop from hours to weeks after hospital admission. Critical illness often leads to increased vasoconstriction, decreased cardiac output, and a pro-inflammatory state which leads to splanchnic hypoperfusion.[94] The cause of stress ulceration in the ICU evolves from several factors including gastric acid secretion, mucosal ischemia, and upper intestinal reflux. This leads to lack of perfusion and oxygen delivery to intestinal cells, resulting in mucosal damage.

CASE 56-7

QUESTION 1: A.K. is a 76-year-old male admitted to the Medical ICU for likely sepsis from a urinary source. He was acidotic on arrival to the emergency department and intubated. He has a past medical history of hypertension, diabetes, multiple pulmonary embolisms, several urinary tract infections, and reports drinking 10 to 12 beers/day. His home medications include metoprolol XL 100 mg daily, metformin 1,000 mg twice daily, atorvastatin 20 mg daily, lisinopril 20 mg daily, and warfarin 7.5 mg daily. Labs on arrival are Na 131 mEq/L, K 3.2 mEq/L, BUN 33 mg/dL, Scr 2.7 mg/dL, Hct 20%, Plt 47 × 10^3/µL, INR 5.9. What risk factors does A.K. have that would qualify him for SUP?

Several risk factors have been identified to help determine who should get SUP. Cook et al.[95] investigated 2,252 ICU patients and found that there were two major risk factors for clinically important GI bleeding: (1) mechanical ventilation for more than 48 hours (odds ratio, 15.6) and (2) coagulopathy (odds ratio, 4.3) defined as a platelet count of <50,000 mm^3, an International Normalized Ratio of >1.5 or a partial thromboplastin time of >2 times the control value.[95] Other risk factors that have been identified include head injury, burn involving >35% of body surface area, partial hepatectomy, hepatic or renal transplantation, multiple trauma with Injury Severity Score of >16, spinal cord injury, hepatic failure, history of gastric ulceration or bleeding during year before admission, and two or more of the following: sepsis, length of ICU stay >1 week, occult bleeding for at least 6 days, and administration of high dose corticosteroids (>250 mg/day of hydrocortisone or equivalent).[96] Most clinicians will start SUP in patients who have ≥1 major risk factor. For patients who have multiple minor risk factors or patient groups excluded from major trials (spinal cord injury, traumatic brain injury, or thermal injury), SUP is determined by the primary team on a case-by-case basis. A.K. has a major risk factor in that he is likely to be intubated for at least 48 hours. For this reason, he should be started on SUP.

CASE 56-7, QUESTION 2: What medication could be initiated in A.K. to reduce his chance of developing a stress ulcer?

The mechanisms to pharmacologically prevent against stress ulcers are to layer the gastric lining with a protective coating, lowering the gastric pH by neutralizing gastric acid secretions, or by preventing gastric acid secretion. The three classes of medications used for SUP are Histamine 2-receptor antagonists (H_2 blockers), proton-pump inhibitors (PPIs), and protective barrier producing medications. A fourth class of medication, prostaglandin analogs, have been used for SUP in the past, but it has not been shown to be beneficial and will not be discussed in this chapter further.[97]

After deciding to start SUP, the next decision to make is what agent to use. The two most commonly used classes of medications are H_2 blockers and PPIs. H_2 blockers were found to be superior to antacids and sucralfate in two different trials.[98,99] There has been a plethora of research comparing PPIs to H_2 blockers, but there still lacks a consensus on what agent to use based on conflicting data. A recent meta-analysis in over 35,000 ICU patients showed H_2 blockers had a lower risk of GI hemorrhage compared to PPIs (6% vs. 2%; adjusted OR, 2.24; 95% CI, 1.81–2.76).[100] This differed with a previous meta-analysis of 13 randomized trials showing reduced GI bleeding in the PPI prophylaxis group compared to the H_2 blocker group (1.3% vs. 6.6%; OR, 0.30; 95% CI, 0.17–0.54).[101] A meta-analysis of 14 trials and 1,720 patients found that PPIs reduced clinically important upper gastrointestinal bleeding and overt upper gastrointestinal bleeding compared to H_2 blockers.[102] Common agents used for SUP are provided in Table 56-4.

An area of debate is whether a patient who is receiving full caloric supplementation through tube feeds requires pharmacologic SUP. Enteral nutrition has been shown to increase gastric pH to >3.5 more often than H_2 blockers or PPIs.[103] Animal models have shown a protective benefit of alimentation on the gastric mucosa from stress-related damage. The practice of whether to discontinue pharmacologic SUP if enteral nutrition has been started varies among different institutions.

CASE 56-7, QUESTION 3: Are there any adverse effects associated with placing A.K. on SUP?

While pharmacologic SUP has shown to decrease bleeding events, it appears this does not come without risk. Gastric acid plays an important part in sterilizing the upper gastrointestinal tract, and alterations of physiologic pH have shown adverse effects. The higher pH level allows increased colonization of potentially pathogenic bacteria in the gastrointestinal tract.

After the implementation of SUP as a standard of care in ICUs, several studies and meta-analyses identified an increased risk of nosocomial pneumonia and C. difficile infections in patients receiving H_2 blockers or PPIs. The increased pH levels as a result of these medications have been proposed as a mechanism of action. Available data are conflicting on the incidence of nosocomial pneumonia among the agents that alter gastric pH. Two studies showed an increased risk for H_2 blockers compared to those who did not receive acid-suppressive therapy or sucralfate.[99,104] One meta-analysis showed no difference on the incidence of nosocomial pneumonia when comparing PPIs to H_2 blockers.[101] A recent study showed that PPIs had a higher incidence of pneumonia compared to H_2 blockers.[100] Both PPIs and H_2 blockers have been associated with an increased risk of C. difficile infection.[105] Most of these studies are observational and did not control for comorbidities, so there is still much debate in the critical care community.

Table 56-4

Common Agents Used for Stress Ulcer Prophylaxis

Agent	Trade Name	Adult Dosing	Routes	Generic Available
Proton Pump Inhibitors				
Dexlansoprazole[a]	Dexilant	30 or 60 mg	Oral	No
Esomeprazole[a]	Nexium	20–40 mg once daily ≥1 hour prior to a meal	Oral, IV	Yes
Lansoprazole[a]	Prevacid	15 or 30 mg once daily before a meal	Oral	Yes
Omeprazole[a]	Prilosec	20 or 40 mg once daily on an empty stomach ≥1 hour before a meal	Oral, IV	Yes
Pantoprazole[a]	Protonix	40 mg once daily (administer suspension 30 minute prior to a meal)	Oral, IV	Yes
Robeprazole[a]	Aciphex	20–60 mg once daily (administer capsule 30 minutes prior to a meal; if capsule is opened and dispersed on food, administer within 15 minutes of preparation)	Oral	Yes
Histamine H_2 Antagonists				
Famotidine[a]	Pepcid	20 mg twice daily (20 mg daily for CrCl <30 mL/minute)	Oral, IV	Yes
Nizatidine[a]	Axid	150–300 mg daily (150 mg/day for CrCl 20–50 mL/minute; 150 mg every other day for CrCl <20 mL/minute	Oral	Yes
Ranitidine[a]	Zantac	150 mg twice daily (150 mg once daily if CrCl <50 mL/minute)	Oral, IV	Yes
Gastric-Coating Agents				
Sucralfate[a]	Carafate	1 g 4 times daily	Oral	Yes

[a] Off label indication for stress ulcer prophylaxis.

While sucralfate does not alter gastric pH, it can interfere with the absorption of many medications including ciprofloxacin, phenytoin, digoxin, and levothyroxine. To help prevent this, sucralfate should be given 2 hours after these medications. Sucralfate has been shown to bind to tube feeds and cause bezoars and cannot be given through duodenal or jejunostomy feeding tubes. There are several options of SUP for A.K. A PPI or H_2 blocker would be the best choice. Since he is intubated and does not have a feeding tube yet, an IV H_2 blocker such as famotidine (renally dosed) or IV PPI such as pantoprazole would be appropriate.

Glycemic Control in ICU Patients

Critically ill patients may develop hyperglycemia for a variety of reasons, including acute illness, preexisting disease states, and the effects of medications. Glycemic goals and treatments differ for patients managed in the ICU as compared to those treated in other settings, including patients receiving chronic therapy for diabetes as outpatients.

CASE 56-8

QUESTION 1: D.M. is a 74-year-old female admitted to the medical ICU for pneumonia and a COPD exacerbation. Her past medical history includes hypertension, hyperlipidemia, and COPD. On the first day of her ICU stay, she decompensates and develops respiratory failure requiring intubation. Among other laboratory abnormalities, her blood glucose concentration is 212 mg/dL. How should clinicians manage D.M.'s hyperglycemia?

A variety of biochemical mediators, such as cortisol, glucagon, catecholamines, and growth factor, may rise in critical illness and contribute to hyperglycemia by increasing glycogenolysis and decreasing gluconeogenesis.[106] In addition to the effects of critical illness, inadequately treated diabetes, adverse effects of drugs like corticosteroids, and exposure to caloric loads from nutritional regimens or dextrose used as a base for intravenous solutions can contribute to hyperglycemia. Although studies suggest that hyperglycemia of critical illness is associated with poor outcomes, it is not clear whether hyperglycemia leads to worsened outcomes or if it is simply an indicator of disease severity.[107–109] In addition to the magnitude of hyperglycemia, glycemic variability has also been associated with negative outcomes.[110]

The optimal blood glucose range for critically ill patients has not been definitely established.[111] Uncontrolled hyperglycemia has the potential to cause severe effects. Single-center studies of surgical and medical ICU patients treated with intensive insulin therapy to achieve blood glucose concentrations between 80 and 110 mg/dL initially suggested improved outcomes, but these findings have not been replicated in subsequent trials.[112,113] In fact, some studies have suggested that aggressive insulin therapy may increase mortality as compared to liberal blood glucose control typically targeting 140 to 180 mg/dL.[114–117] It has been suggested that the higher rates of hypoglycemia observed in patients receiving intensive insulin may increase mortality by leading to neurologic complications. On the basis of these findings, most clinicians attempt to maintain patients' blood glucose concentrations between 140 and 180 mg/dL. Since parenteral administration of insulin achieves more rapid and reliable results than oral therapy, patients are typically managed with subcutaneous insulin or intravenous insulin infusions while in the ICU. Subcutaneous regimens typically include as-needed sliding scale insulin involving rapid or short-acting formulations. Scheduled long-acting insulin may be combined with sliding scales in some patients; however, clinicians should cautiously dose insulin in order to avoid hypoglycemia. Some patients with significant insulin needs may benefit from a continuous intravenous infusion of regular insulin that is carefully titrated to the blood glucose goal.

Since D.M.'s blood glucose exceeds 180 mg/dL, clinicians should attempt to achieve better glycemic control. First, dextrose-containing fluids should be minimized, and any enteral nutrition she is receiving should be evaluated. Medications, like steroids, that might increase her blood glucose concentrations should be assessed and minimized as possible. If her blood glucose remains high after these measures, it would be appropriate to initially consider sliding scale insulin with regular insulin.

Multiple Sclerosis

Melody Ryan

CORE PRINCIPLES

		CHAPTER CASES
1	Multiple sclerosis (MS) is a chronic inflammatory and degenerative disease of the central nervous system in which demyelination and axonal damage occur. MS can take one of several forms: relapsing-remitting, secondary-progressive, or primary-progressive are the most common forms.	**Case 57-1 (Questions 1, 5), Figure 57-1**
2	The diagnosis of MS is based on clinical symptoms and is supported by magnetic resonance imaging (MRI) and laboratory testing (cerebrospinal fluid oligoclonal bands and immunoglobulin G synthesis rate; evoked potential testing). In an individual patient, dissemination in space and time must be demonstrated before the diagnosis of MS is made.	**Case 57-1 (Questions 1, 5)**
3	Glucocorticoids are the agents of choice for treatment of acute MS relapses.	**Case 57-1 (Question 7)**
4	Clinically isolated syndrome (CIS) is a term used to describe a first demyelinating neurologic event before the diagnosis of MS has been made. When a patient presents with CIS and MRI abnormalities, progression to clinically definite MS is likely, and therapy with interferon β, glatiramer acetate, or teriflunomide helps to prevent this progression.	**Case 57-1 (Questions 1, 2)**
5	Dimethyl fumarate, glatiramer acetate, interferon β-1a, interferon β-1b, and teriflunomide are potential first-line therapies for relapsing forms of MS. The choice of treatment is often based on provider or patient preference.	**Case 57-1 (Questions 3, 5–8) Case 57-2 (Question 1), Table 57-3**
6	Adherence to self-injection therapy with interferon β-1a, interferon β-1b, and glatiramer acetate is low.	**Case 57-1 (Question 4), Table 57-7**
7	Alemtuzumab, fingolimod, mitoxantrone, and natalizumab therapy is generally reserved for patients with worsening relapsing forms of MS because of adverse effect concerns.	**Case 57-1 (Question 7) Case 57-2 (Question 3)**
8	Patients with MS can experience many symptoms, such as walking problems or impaired ambulation, sexual dysfunction, pain, bladder dysfunction, fatigue, cognitive dysfunction, spasticity, bowel dysfunction, dysphagia or dysarthria, and pseudobulbar affect. These symptoms may require both nonpharmacologic and pharmacologic therapy.	**Case 57-1 (Question 10), Case 57-2 (Question 4), Table 57-2 and 57-4**

EPIDEMIOLOGY, NATURAL COURSE OF THE DISEASE, AND PROGNOSIS

Multiple sclerosis (MS) is a chronic inflammatory and degenerative disease of the central nervous system (CNS) in which demyelination and axonal damage occur.[1] The disease has a mean age at onset of 30 years, with diagnoses typically occurring between the ages of 20 and 50 years.[2],[3] Because of the young age at onset, MS has a dramatic effect on employment and, in fact, is the most common cause of disability in young adults.[4] Overall life expectancy is decreased by about 6 years compared with age- and sex-matched control subjects,[5] and patients are three more likely to die than the general population when matched for age and sex.[5] Infection and cardiac causes of death are the most commonly reported, similar to a control population, but occurring in higher frequencies in patients with MS.[5],[6] Health-related quality of life

is lower in patients with MS than in the general population, and this decrease is related to the severity of MS.[7]

MS affects approximately 0.1% of the US population (400,000 people) and about 2.5 million people worldwide.[3],[4] Women are 2 to 3 times more likely to have MS than men.[3] Many environmental and genetic factors have been associated with MS (Table 57-1); however, the causal nature of any of these factors has yet to be established.[8–18] Current thought is that an environmental trigger acting in a genetically susceptible individual is the probable cause of MS.[19]

MS is most frequently encountered between 40 and 60 degrees north or south latitude. Regions with a high prevalence include Western and Northern Europe, Canada, Russia, Israel, Northern United States, New Zealand, and Southeast Australia.[20] Additionally, relapse rates may also vary seasonally with latitude.[21] This finding has spurred many research studies and hypotheses. One hypothesis is that development of MS is related to sunlight exposure or vitamin D. Higher serum concentrations of 25-hydroxyvitamin D (the major circulating form and the one that is measured by clinical laboratory testing) are associated with reduced hazard of an MS relapse, and lower concentrations are associated with higher rates of MS diagnoses.[22],[23] Genetically, lack of the vitamin D receptor (VDR) and CYP27B1 (encodes the enzyme responsible for vitamin D activation converting 25-hydroxyl-vitamin D to 1,25-hydroxyl-vitamin D) is associated with impaired immune system.[24] Some investigators have found links between season of birth and development of MS, suggesting that maternal vitamin D status may be important.[24] Relapses also follow a seasonal pattern, with peaks in the early spring and troughs in the autumn in both hemispheres, further suggesting a role of vitamin D in relapses.[21]

Epstein–Barr virus is a ubiquitous infection; however, high EBV titers and a history of infectious mononucleosis both increase risk of developing MS. Smoking is a risk factor, with higher levels of smoking conferring greater risk.[17],[24] Dietary salt intake may be associated with higher relapse rates and increased numbers of brain lesions.[18]

There is likely a genetic predisposition to development of MS. First-degree relatives of people with MS have a risk of MS that is 10 to 25 times greater than the general population; the concordance rate in identical twins is 35%.[11],[13] There are probably several genetic factors that increase risk for MS, including HLA type and various single-nucleotide polymorphisms that control T-cell receptors, vitamin D receptors, and estrogen receptors.[23],[25],[26] A specific major histocompatibility complex (MHC) associated with MS is HLA-DRB1*1501 class II, but over 100 different genetic variations have been associated with MS.[24] No genetic association has been found for a particular clinical course or rate of progression.[24]

Although MS is more prevalent in Caucasian populations in the United States, there is evidence that African-American patients may be more likely to have primary-progressive forms and may have a more severe disease course.[27–29]

Table 57-1

Factors Associated with Multiple Sclerosis (MS)

Female sex[3,8]	Low sun exposure[9,10]
Caucasians[11]	Low serum concentrations of vitamin D (25-hydroxyvitamin D)[10]
Higher latitudes of residence[12]	Northern European heritage[13]
High serum antibody titers to the Epstein–Barr virus nuclear antigens[14,15]	Tobacco smoking[14,16]
Infectious mononucleosis[17]	Dietary salt[18]

MS is generally characterized as one of three main types according to the presentation and clinical course of the disease: relapsing-remitting MS, secondary-progressive MS, and primary-progressive MS. These three types of MS are distinguished by their natural histories. Relapsing-remitting MS was named for the relapses (also called exacerbations or attacks) of clinical disease activity that alternate with periods of symptom remission. Recovery during the remission periods can be complete, or the patient may continue to have some clinical deficits.[30] Between 80% and 90% of patients have relapsing-remitting MS when they are first diagnosed.[1],[31] Patient registry data provide insight regarding the prognosis of those with relapsing-remitting MS. Patients diagnosed with relapsing-remitting MS at onset have slower progression to disability than patients with primary-progressive MS; patients having complete or near-complete recovery from the first attack of MS have a longer time to disability compared with those with significant persistent deficits after the first attack.[1],[31]

Approximately 80% of patients initially diagnosed with relapsing-remitting MS experience a secondary-progressive form in which fewer relapses occur, but disability continues to progress.[1],[2] The cause of the conversion from relapsing-remitting MS to secondary-progressive MS is unknown, but it has been hypothesized that the change occurs when axonal loss in the CNS reaches a critical threshold.[32] The time to development of secondary-progressive MS is quite variable. The usual time to conversion is 20 to 25 years after diagnosis, with a median patient age at the time of conversion of 43 years; however, it may occur much sooner.[1],[30],[33] It is not known how treatment affects this process. In one study, the number of early relapses (within 2 years of diagnosis) was associated with a shorter time to development of secondary-progressive MS.[34] Therefore, early treatment with a therapy that reduces relapses might be expected to delay development of secondary-progressive MS.

Approximately 10% to 15% of patients have primary-progressive MS.[1],[35] This type of MS is progressive from onset with occasional minor improvements or periods of stabilization.[30] Primary-progressive MS is more common in patients who are older than 50 years at diagnosis.[1] Select studies have found this form to be more common in men, but others have found no association with sex.[1],[35] Mean time from diagnosis to requiring a cane to walk is approximately 9 years for patients with primary-progressive MS.[36]

In the absence of treatment, patients who initially present with relapsing-remitting MS develop average Expanded Disability Status Scale (EDSS) scores of 4.0 or higher (indicating significant disability) by 7 years after diagnosis.[20] The EDSS is a scale commonly used in MS to measure level of disability and progression of the disease.[37] Some predictors of a more progressive disease course include male gender, multisystem symptoms, incomplete recovery from the initial episode, progressive disease from the time of diagnosis, older age at onset, and abnormal baseline magnetic resonance imaging (MRI) results.[30],[38] Although patients present with different types of MS, once progression begins, all forms of progressive MS follow a similar time course for subsequent progression.[30]

A new classification system has been proposed which denotes disease activity and progression.[39] Patients with new, active MRI lesions or with clinical relapses within a specified time frame are classified as active, whereas those without new lesions or relapses are classified as inactive. In a similar way, patients are categorized as progressing if they have steadily increasing objectively documented neurologic dysfunction without recovery or non-progressing. For example, a patient with relapsing-remitting MS who has had a clinical relapse in the last year, but who had full recovery, would be classified as relapsing-remitting MS-active and not progressing.[39] Because MS begins during young-to-middle adulthood, there is a large economic burden associated with the disease. One study in which newly diagnosed patients were matched to healthy control subjects found that patients with MS were 3.5 times as likely to be hospitalized, twice as likely to have at least one emergency department visit, and 2.4 times as likely to have at least one visit for physical, occupational, or speech therapy during the course of a year.[40] These additional services were associated with higher mean annual all-cause healthcare costs ($32,051 vs. $4,732 for MS patients and control subjects, respectively).[41] These estimates do not consider the loss of employment or loss of caregiver employment. When these factors are taken into consideration, the cost of MS is more than $77,938/year.[42]

Ten years after diagnosis, 50% to 80% of patients with MS are unemployed. Surprisingly, only 15% of unemployment is related to physical restrictions.[34] Of the factors most often cited as leading to unemployment, only decreased walking ability relates to physical disability. The other common factors are increased age, decreased verbal fluency, and loss of memory.[34],[42]

PATHOPHYSIOLOGY

Many aspects of the pathophysiology of MS remain unclear, although research in this area is progressing rapidly. Foremost in unresolved issues is the identity of the actual initiating factor for the autoimmune and inflammatory processes that characterize MS. Through the years, several dozen triggers have been proposed. Current thinking is that a genetically susceptible individual has an environmental factor which triggers the immune system to cause MS.[44]

There are two pathologic processes that occur during MS. The first is inflammatory. During this process, the body mounts an autoimmune attack on the myelin covering of nerve fibers of the white matter in the CNS. These areas of demyelination are visualized as plaques or lesions and are seen on brain tissue directly (e.g., on autopsy) or on MRI with contrast agents (Fig. 57-1).[25] It is this inflammation that causes the relapses that are seen clinically, and it is the resolution of these relapses that is seen as remission.

The second process is neurodegenerative, during which the axons of nerves in brain white matter are damaged, some irrevocably. This neurodegeneration causes a progressive disability when transmission through the nerve cell is slowed or fails completely. It is cumulative with time and may be irreversible. It is not known whether the inflammatory or neurodegenerative process occurs first in MS or whether they are simultaneous.[19]

Inflammation

The inflammatory cascade in MS is complex. Various types of T cells play a role early in the process.[4] The unknown antigen couples with MHC molecules.[14],[44]

These antigen–MHC pairs encounter antigen-presenting cells (APC) such as dendrites, macrophages, and microglia.[9],[20] T cells recognize this antigen–MHC–APC complex, become activated, and initiate the immunologic cascade.[4]

Under normal circumstances, regulatory T cells (T_{reg}) monitor for and control autoimmune T-cell formation in the periphery. It has been hypothesized that T_{reg} cells malfunction in people with MS.[19]

The activated T cells then retreat to the lymphatic tissues in the body, such as the spleen and lymph nodes, to expand.[4] At the appropriate time, the T cells exit the lymphatic tissues and rejoin the circulation. Sphingosine-1-phosphate (S1P), a small, circulating lipid molecule, is important in this process. For the T cells to exit the lymphatic tissues, the S1P receptor 1 must be expressed on their surface.[46] The T cells follow an S1P concentration gradient to exit the lymphatic tissues and join the circulation.

The activated T cells must cross the blood–brain barrier to attack myelin in the CNS. An adhesion molecule, $\alpha_4\beta_1$-integrin (VLA4), is found on the surface of T cells.[25] When the T cells approach the blood–brain barrier, they slow and bind to the α_4-integrin and p-selectin glycoprotein ligand 1. This bonding allows the T cells to transmigrate through the endothelial cells of the blood vessel.[46]

Now in the perivascular space, the T cells must be reactivated by new APC.[4] Through the action of matrix metalloproteinases 2 and 9, the activated T cells invade the parenchyma of the brain.[46] Once ensconced in the brain, the T cells begin to secrete various proinflammatory cytokines that further stimulate the inflammatory cascade, including stimulation of microglia.[25],[47],[48]

The microglia produce proteolytic enzymes, lipolytic enzymes, reactive oxygen species, reactive nitrogen species, excitotoxins, and more proinflammatory cytokines. Activated microglia can also serve as APCs for activation of additional T cells.[47] Nitric oxide, a reactive nitrogen species, is increased during inflammation and can inhibit mitochondrial respiration, inhibit the sodium–potassium adenosine triphosphatase pump, and cause the intracellular release of calcium. The excess calcium leads to degenerative processes within the cell.[4],[32]

Although the role of T cells is central to MS pathology, the role of B and NK cells is much less clear. B cells may be involved in antigen presentation and the production of the immunoglobulin found in the CSF of patients with MS.[19] NK cells have been postulated to have both helpful and deleterious effects.[19]

At some point, the resolution of inflammation begins. During the inflammatory cascade, myelin is broken down, and this myelin debris inhibits remyelination. The microglia use phagocytosis to clear myelin structures, axons, apoptotic cells, and myelin debris from the area of inflammation.[47] After this process, the microglia begin to produce immunomodulatory cytokines.[47] Helper T type 2 cells become more prominent and begin secreting immunomodulatory cytokines as well.[47]

Remyelination then begins; however, some evidence suggests that the ability of the body to remyelinate decreases with age.[4]

p. 1220

---

p. 1221

Microglia produce more cytokines and some growth factors that cause oligodendrocyte progenitor cells to migrate to the area. Remyelination occurs when oligodendrocyte progenitor cells differentiate into new oligodendrocytes.[47] S1P receptors 1 and 5 present on oligodendrocytes appear to help with differentiation.[49] Remyelination may not be complete and, in some cases, does not occur at all. The myelin also may be thinner and shorter than the original myelin.[4]

Neurodegeneration

Axonal injury can occur throughout the course of the disease and may even occur before any clinical symptoms.[3,50] Inside chronic MS lesions, there are 60% to 70% fewer axons compared with other white matter in the same patient.[32] In addition to producing myelin, oligodendrocytes support axons through production of insulin-like growth factor type I and neuregulin; thus, axons can die without the support of the oligodendrocytes. However, axonal loss has been demonstrated at sites separate from MS lesions, particularly the thalamus.[4,32,50] Although oligodendrocytes provide trophic support for the axons, they also inhibit new growth to prevent random neurite sprouting. Three myelin-associated inhibitor factors, myelin-associated glycoprotein, Nogo-A, and oligodendrocyte myelin glycoprotein, lie in the sheath of myelin closest to the axon, where they prevent this sprouting.[3]

Microtubules are also important for neurite growth. The assembly of microtubules is controlled by collapsin response mediator protein 2 (CRMP-2).[3] When CRMP-2 is phosphorylated, neurite growth is inhibited.[3] Ras homolog gene family, member A (RhoA)–guanosine triphosphate (GTP), has action on both the myelin-associated inhibitory factors and CRMP-2. The myelin-associated inhibitory factors signal RhoA–GTP to neurite retraction rather than growth.[3] It also activates Rho kinase, which phosphorylates CRMP-2.[3]

Myelin normally allows saltatory, fast conduction (i.e., conduction via leaps) at the nodes of Ranvier; thus, loss of myelin slows or prevents transmission of nerve impulses.[4]

In the demyelinated state, sodium channels under the myelin sheath may become functional to allow improved nerve conduction.[32] The activation of sodium channels results in sodium entry into the cell. The excess sodium activates the sodium–calcium exchanger to export sodium and import calcium, fueling the degenerative processes within the neuron.[4],[32] Additionally, increased numbers of glutamate-regulated α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors are seen in demyelinated axons. Activation of these receptors results in increased levels of intracellular sodium and calcium, further contributing to neurodegeneration.[32]

CLINICAL PRESENTATION

Because the demyelination associated with MS can occur in any part of the CNS, many different symptoms are associated with the disease. At first presentation, the most common clinical symptoms are sensory disturbances, particularly of the extremities, partial or complete visual loss, motor dysfunction of the limbs, diplopia, and gait dysfunction.[20] Two demyelinating syndromes are so distinct and they have been recognized, named, and deserve particular mention: optic neuritis and transverse myelitis. Optic neuritis is the acute demyelination of the optic nerve. Symptoms may include ocular pain, blurred vision, or changes in color perception.[51] Transverse myelitis is impairment of motor control or sensory function, or control over bladder, bowel, and sexual functions that are consistent with a lesion at a specific point in the spinal cord, but without a structural cause such as a herniated disc.[51]

Table 57-2

Common Symptoms in Chronic Multiple Sclerosis

Symptom	Prevalence (%)
Sexual dysfunction[57]	85
Walking problems or impaired ambulation[58]	64
Pain[59]	30–90
Bladder dysfunction[60]	75
Fatigue[61]	74
Cognitive dysfunction[62]	70
Spasticity[59]	60
Bowel dysfunction[60]	50
Depression[63]	50

Dysphagia or dysarthria[64]	40
Pseudobulbar affect[65]	10

As concern has developed about neurodegenerative changes that occur early in the course of MS, there has been more interest in very early treatment after the emergence of symptoms to delay or decrease the development of MS. The term clinically isolated syndrome (CIS) describes a first demyelinating neurologic event involving the optic nerve, cerebrum, cerebellum, brainstem, or spinal cord.[51] Up to 85% of people with MS may first present with CIS.[52] Of those who present with CIS, 63% will develop MS during the ensuing 20 years.[52]

Patients younger than 40 years old are more likely to convert from CIS to clinically definite MS than those ≥40 years.[53] Patients with optic neuritis as the presenting diagnosis are less likely than those with other symptoms to develop clinically definite MS. The presence of oligoclonal bands in the CSF, low serum concentrations of vitamin D, and multiple lesions on MRI are associated with a particularly high risk of development of MS.[53],[54]

Occasionally, MS-type lesions will be visible on an MRI scan performed for other reasons. If the patient has no other symptoms, this condition is known as radiologic-isolated syndrome.[55] About 30% of these patients have a clinical episode within 5 years of the detection of their MRI abnormality.[56] Younger patients, males, and those with lesions on the spinal cord were more likely to develop a CIS.[56] No treatment is suggested for patients with these findings at this time.[56]

With time and with neurodegeneration, many other symptoms can develop in people with MS. The most common symptoms are listed in Table 57-2.[57–65]

DIAGNOSIS

When patients first present for medical care with symptoms of MS, diseases as diverse as infections, cancers, vascular disease, or other inflammatory demyelinating diseases are commonly part of the differential diagnosis. Thus, the addition of MRI and other laboratory findings can help with the diagnosis. At other times, the diagnosis is not apparent until the occurrence of a second attack.[66]

Various diagnostic criteria have been proposed in an effort to standardize diagnoses of MS and to promote earlier treatment. The initial criteria stated that the patient must have experienced at least two demyelination-related episodes separated by time

and space (i.e., at least two episodes involving distinct regions of the CNS).[67]

Guidelines proposed in 2001 and revised in 2005 and 2010 allow for the use of MRI and CSF findings to fulfill these criteria after an initial clinical attack.[68–70] Primary-progressive MS is diagnosed when there is continuous progression of neurologic symptoms during a 1-year period with characteristic MRI and CSF findings.[70]

OVERVIEW OF TREATMENT

Although the mechanisms of action of MS pharmacotherapies are diverse, they all can be generally categorized as immunomodulating agents. To date, all therapies for MS have targeted the inflammatory response rather than the accompanying neurodegeneration features of the disease.

Treatment of Acute Relapses

Corticosteroids are used in the treatment of MS to control inflammation during acute relapses. Although most patients respond to treatment with corticosteroids, some do not. These agents have several actions that contribute to their acute anti-inflammatory effects. Corticosteroids increase the activity of T_{reg} cells, reduce the activity of T and B cells, reduce adhesion molecule production, and reduce proinflammatory cytokines.[71–73]

Treatment of Relapsing-Remitting Multiple Sclerosis

Most of the therapeutic research conducted in MS has focused on the relapsing-remitting form of the disease. This is the most common form of MS at presentation, and it has an important inflammatory aspect. The agents that are currently US Food and Drug Administration (FDA)-approved for MS include alemtuzumab, beta interferons, dimethyl fumarate, fingolimod, glatiramer acetate, mitoxantrone, natalizumab, and teriflunomide.

ALEMTUZUMAB

Alemtuzumab is a monoclonal antibody aimed at CD52. It reduces the population of circulating B and T cells. The peripheral circulating lymphocytes are undetectable within minutes of infusion.[74] These cells repopulate, but fairly slowly; B cells have a median recovery time of 8 months, $CD8^+$ T cells 20 months, and $CD4^+$ T cells 35 months. However, some patients took as long as 12 years to reach baseline levels.[75] Alemtuzumab reduced relapses and MRI lesions compared to interferon β-1a subcutaneously, but had similar rates of disability progression; 77% of patients taking alemtuzumab were completely relapse-free at 2 years.[76] One long-term study saw benefits sustained from alemtuzumab over 5 years.[77]

BETA INTERFERONS

Beta interferons are thought to work by suppressing T-cell activity, downregulating antigen presentation by MHC class II molecules, decreasing adhesion molecules and matrix metalloproteinase 9, and increasing anti-inflammatory cytokines while decreasing proinflammatory cytokines.[4],[47],[48],[78] There are two types of interferon β (interferon β-1a and interferon β-1b) and a total of four preparations available to treat MS (Table 57-3).[79–82] Placebo-controlled trials of each of the interferon β agents have shown a reduced number of relapses and decreased disease progression measured on the EDSS in patients treated with interferon versus those who were given placebo.[83–85]

Table 57-3

Interferon β Preparations Used in the Treatment of Multiple Sclerosis[79–82]

Interferon Type	Route of Administration	Frequency of Injection
Interferon β-1a	Intramuscular	Weekly
Interferon β-1a	Subcutaneous	3 times weekly
Interferon β-1b	Subcutaneous	Every other day
Peginterferon β-1a	Subcutaneous	Every 2 weeks

Data are available for patients who have been treated with interferon β-1b for up to 16 years. A sustained reduction in relapse rate of 40% was seen in patients who received the drug continuously, an improved response compared with those who received placebo or interferon only for a short time. Patients who received continuous interferon therapy also had slower rates of disease progression.[86],[87] Eight-year follow-up data for interferon β-1a given intramuscularly did not show this sustained reduction in relapse rate, but did show that those who began treatment earlier had better long-term outcomes.[86]

DIMETHYL FUMARATE

Dimethyl fumarate is rapidly cleaved in the intestine to form its active form, monomethyl fumarate. The medicine causes a shift in cytokine production from interferon γ and tumor necrosis factor α to interleukin-4 and -5.[88] Dimethyl fumarate also activates the antioxidant effects of nuclear 1 factor (erythroid-related 2)-like 2 (Nrf2) transcriptional pathway which may assist with the neurodegeneration in multiple sclerosis.[88] Dimethyl fumarate reduces the relapse rate by about half and new lesion development on MRI scan compared to placebo.[89]

FINGOLIMOD

Fingolimod is an S1P receptor modulator.[4] It binds to the S1P receptor 1 expressed on T cells.[49] This binding causes the receptor to be internalized in the T cell, where it is unresponsive to the normal signal to exit the lymphoid tissues and recirculate.[49,90] Without the T cells circulating, they are not activated and this disrupts the inflammatory cycle. Fingolimod has been shown to decrease the relapse rate by about half compared with placebo as well as to reduce disability progression.[91,92]

GLATIRAMER ACETATE

Glatiramer acetate decreases type 1 helper T (T_H1) cells while increasing type 2 helper T (T_H2) cells. Additionally, it increases production of nerve growth factors.[4,78] The short-term and long-term efficacy of glatiramer acetate is similar to that of the interferons.[86,93] Regimens of 20 mg subcutaneously daily and 40 mg subcutaneously 3 times weekly are effective compared to placebo.[94]

MITOXANTRONE

Mitoxantrone works as a general immunomodulator. It decreases monocytes and macrophages and inhibits T and B cells.[4] Compared with placebo, mitoxantrone decreased the number of exacerbations and improved MRI in treated patients.[95,96]

NATALIZUMAB

Natalizumab is a humanized monoclonal IgG4 antibody. It blocks T-cell entry into the CNS by binding to $\alpha_4\beta_1$-integrin located on the lymphocyte to keep it from binding to the vascular cell adhesion molecule-1 on the endothelial cell.[4,97,98] In clinical trials, natalizumab was very effective, reducing the 1-year relapse rate by 68%, the risk of progression of disability in 2 years by 42%, and new lesions on MRI by 83%.[99]

TERIFLUNOMIDE

Teriflunomide is the active metabolite of leflunomide. It is thought to act in MS by blocking de novo pyrimidine synthesis, inhibiting B- and T-cell division, and blocking the inflammatory pathway prominent in MS.[100] It may also inhibit the pairing of T cells and APC to prevent T-cell activation. Teriflunomide reduces the annualized relapse rate by about 20% to 30% and reduces the risk of new MRI lesions by 60% to 80% compared to placebo in clinical trials.[101,102]

Treatment of Progressive Forms of Multiple Sclerosis

Patients with both secondary-progressive and primary-progressive MS may experience relapses. In these cases, all of the agents used for relapsing-remitting MS may be useful to reduce the number of relapses.[103–106] Some evidence suggests that therapies (specifically, interferon β-1a) are less effective for secondary- progressive MS than for relapsing-remitting MS.[104],[106] This finding is consistent with the known mechanisms of action for the currently available agents, which are directed at the inflammatory processes. Treatment of progressive forms of MS is an area in urgent need of scientific investigation. Recently (March 2017), the FDA approved Ocrevus (ocrelizumab), that is the first agent for primary-progressive MS.

Symptom Management

As disability increases, many patients with MS exhibit other associated symptoms that require targeted treatment (Table 57-2).

BLADDER, BOWEL, AND SEXUAL DYSFUNCTION

Bladder, bowel, and sexual dysfunction are very common in patients with MS. Up to 75% of patients have bladder symptoms; constipation or bowel incontinence occur in approximately 50% of patients; and sexual dysfunction occurs in 84% of men and 85% of women.[57],[60] It is also known that those patients with more bladder symptoms or sexual dysfunction have lower quality of life compared with patients without these problems.[57],[107] The treatment approaches for sexual dysfunction and urinary incontinence in MS are similar to those used when these symptoms occur as part of a primary disorder.

IMPAIRED AMBULATION

In a survey commissioned by the National MS Society, 64% of patients with MS stated that they had some limitation to their walking ability and, therefore, limited activities that involved walking.[58] Physical therapy and conditioning may be of some help for this problem.[59] Another approved treatment option is extended-release dalfampridine. This agent blocks potassium channels and prevents repolarization of the cell, thus prolonging action potentials and nerve impulse transmission in the demyelinated axon.

In clinical studies of extended-release dalfampridine, 57% of treated patients were unable to decrease the amount of time it took them to walk 25 feet. The 43% who did decrease their time were considered responders. On average, they improved their speed to walk 25 feet by 25% (approximately 3 seconds faster).[108] Clinically, it may be difficult to determine which patients respond well to extended-release dalfampridine without conducting timed 25-foot walks.[59]

Adverse effects associated with extended-release dalfampridine include urinary tract infections, insomnia, dizziness, headache, and nausea. Seizures are a less common adverse effect and are related to dose and use of immediate-release dalfampridine. Therefore, this agent is contraindicated in patients with a history of seizures.[109]

PAIN

Between 30% and 90% of patients with MS report experiencing pain.[59] Pain related to MS is of two types: non-neurogenic and neurogenic. Non-neurogenic pain is often related to paralysis, immobility, or spasticity; examples include tension-type headache, low back pain, and limb pain associated with poor mobility or postural changes.[110] Physical therapy, repositioning limbs, and typical analgesics may be effective for treatment of non-neurogenic pain.

A number of painful neurogenic conditions have been described in association with MS (Table 57-4).[111] Patients often describe neurogenic pain as having a burning, aching, pricking, stabbing, or smarting quality.[112] Atypical analgesics are used for neurogenic pain. For trigeminal neuralgia, carbamazepine and oxcarbazepine are first-line treatments.[112] Baclofen, lamotrigine, gabapentin, topiramate, misoprostol, pimozide, or tocainide may be helpful as second-line treatments.[59],[112] Surgical options may provide relief if drug treatments are ineffective.[59],[112] Antiepileptic medicines and antidepressants are also commonly used for other types of neurogenic pain.

FATIGUE

Often described as the most disabling symptom by patients with MS, 74% experience fatigue.[59],[61] The reason that patients exhibit fatigue is not well understood; however, hypotheses include direct effects of cytokines, axonal loss, or cortical disorganization.[63],[113] Conduction is impaired in demyelinated axons, and increases in temperature may further worsen conduction.[113] However, fatigue may be caused or worsened by other mechanisms such as sleep dysfunction, depression, or medication adverse effects.[64],[114]

Nonpharmacologic approaches are often the mainstay of therapy for fatigue and may include interventions to improve sleep quality, treatment for depression when present, improvements in diet, and increased physical activity.[59] Cognitive behavioral therapy has been helpful for some patients.[63] Cooling therapy with jackets worn over large areas of the body and magnetic therapy have demonstrated benefit in clinical trials.[115–117] Acupressure was shown to help women with fatigue in a small study.[118]

Table 57-4

Types of Neurogenic Pain Associated with Multiple Sclerosis[59,110]

Trigeminal neuralgia—sudden, usually unilateral, severe, brief, stabbing, recurrent episodes of pain in the

distribution of one or more branches of the trigeminal nerve.[111]
Lhermitte's phenomenon—sudden onset, brief, electric shock-like sensation traveling rapidly down to the spine or into the arms or legs. Usually caused by flexing the neck. Sometimes occur occasionally for short periods.
Tonic spasms
Burning dysesthesia of the limbs and trunk
Migraine headache

The only pharmacologic therapy for fatigue with proven benefit is amantadine; however, the clinical trials for this agent have included small numbers of patients.[119] Sustained-release fampridine may be helpful in some patients.[120] Modafinil has been used in two placebo-controlled studies, but neither trial showed significant differences in response between modafinil and placebo.[121],[122]

COGNITIVE DYSFUNCTION

Cognitive dysfunction may occur early in the course of the disease and has a negative impact on quality of life.[33] Among patients with CIS, 29% had cognitive impairment at the time of presentation. The only predictor of cognitive impairment was the number of lesions on MRI.[123] Between 40% and 70% of MS patients eventually have some cognitive dysfunction.[59] The most common problems are memory impairment, slowed speed of information processing, decreased mental flexibility, and impaired executive functioning.[62] Cognitive dysfunction can also limit the ability of patients with MS to understand discussion of disease and treatments.[124] Breaking down discussions into various components (e.g., intended effects, adverse effects) helps with understanding.[124]

Nonpharmacologic interventions such as cognitive rehabilitation to develop the use of intact cognitive skills to compensate for areas of poor cognitive performance may be beneficial.[125],[126] Treatment of MS with immunomodulatory drugs has shown some benefit for cognitive impairments.[127] Additionally, small studies of acetylcholinesterase inhibitors were promising.[128–130] However, trials of memantine, amantadine, pemoline, and gingko biloba have all been negative.[59],[130]

SPASTICITY

Spasticity can be defined as an increased resistance of muscle to an externally imposed stretch.[131] Approximately 60% of patients with MS exhibit spasticity, which may worsen with other noxious stimuli such as a full bladder or colon, infection, or MS exacerbations.[59],[131] Complications from spasticity may include pain, spasms, reduced mobility, limited range of movement, contractures, fatigue, poor quality of sleep, cardiopulmonary deconditioning, decubitus ulcers, and skin breakdown.[59],[131] Nonpharmacologic therapies, such as repositioning physical therapy, stretching, or splinting, may help with spasticity.[131] These efforts are usually most successful with spasticity that is localized to one area of the body. Injection of intramuscular botulinum toxin can also be beneficial for localized spasticity.[59] Spasticity that is generalized to many areas of the body is best addressed with systemic therapy in addition to nonpharmacologic treatments. Baclofen and tizanidine are first-line therapies for spasticity. Gabapentin, benzodiazepines, and dantrolene are considered second-line agents.[59] In severe cases, intrathecal baclofen can be delivered via infusion pump through a catheter into the intrathecal space.[59] Cannabinoids have been studied with some success for patient-reported improvements in spasticity, but there is little objective evidence for effect.[117],[132],[133] There is no FDA-approved indication for this use in the US.

PSYCHIATRIC DYSFUNCTION

Psychiatric problems including depression, bipolar disorder, pseudobulbar affect (emotional lability), and psychosis all occur at increased rates in MS patients compared with the general population.[134–136] Depression can affect up to 50% of patients with MS.[63] Several clinical trials of depression treatment have been conducted in patients with MS. In these, cognitive behavioral therapy has been shown to be possibly effective, and fluoxetine and sertraline have been shown to have benefit in some trials.[59],[137]

Pseudobulbar affect occurs in approximately 10% of patients with MS and involves frequent and inappropriate episodes of crying, laughing, or both, which may be unrelated to underlying mood. The exact cause of pseudobulbar affect is not known, but it may be caused by disruption of neural pathways from the brainstem and cerebellum. Serotonin, dopamine, and glutamate also appear to be important in the development of pseudobulbar affect. It is not isolated to patients with MS, but may also occur in other neurologic disorders such as stroke. This disorder can be socially stigmatizing and highly disabling.[138–140]

When used together, dextromethorphan and quinidine have shown efficacy for pseudobulbar affect, and a combination product is approved for this indication by the FDA. Dextromethorphan is an agonist at σ-1 receptors, suppressing release of excitatory neurotransmitters, and an antagonist at N-methyl-D-aspartate glutamate receptors.[138] Dextromethorphan is metabolized by cytochrome P-450 (CYP) 2D6 to dextrorphan, which does not cross the blood–brain barrier. When a low dose of quinidine, a CYP 2D6 inhibitor, is added, dextromethorphan serum concentrations are increased 20-fold. In a 12-week study of 283 patients, a 49% improvement in inappropriate emotional episodes was demonstrated.[140]

Complementary and Alternative Medicine

Several clinical trials are ongoing to evaluate the therapeutic potential of vitamin D supplementation in patients with MS.[141] In one study, 49 patients with MS were randomly assigned to receive open-label vitamin D or no active treatment (control group). The treatment group was given vitamin D to rapidly raise the serum 25-hydroxyvitamin D concentrations, starting with 4,000 international units/day and increasing to 40,000 international units/day during 28 weeks. In the second phase, subjects were administered 10,000 international units/day for 12 weeks. There was a reduction in annualized relapse rate and a higher proportion of relapse-free patients in the vitamin D group compared with the control group.[141] Another study added 20,000 international units/week of vitamin D or placebo to interferon β-1b. The group given vitamin D had decreased brain lesions on MRI after 1 year of treatment.[143] One study did not find benefits.[144] The results of these trials should be interpreted cautiously, however, because of their small numbers of patients. Vitamin D cannot be taken with impunity, however. An Institute of Medicine reports cautions against intake of more than 10,000 international units daily because of associations with kidney and tissue damage. Elevated serum concentrations of vitamin D have also been associated with hypercalcemia, anorexia, weight loss, polyuria, heart arrhythmias, vascular and tissue calcification, increases in all-cause mortality, some cancers, cardiovascular disease risk, fractures, and falls. Thus, the recommended dietary allowance for adults is 600 IU/day with an upper intake limit of 4,000 IU/day.[145]

CASE 57-1

QUESTION 1: C.B. is a 32-year-old woman of Finnish descent who presents to the neurology clinic with slurred speech and double vision. These symptoms began 2 weeks ago and have not changed. C.B. saw her primary-care physician at that time, who referred her to the neurology clinic. Her past medical history is unremarkable other than a normal gestation and vaginal delivery of a female infant 3 years ago. Today her vital signs are a blood pressure of 126/82 mm Hg, heart rate of 78 beats/minute, respirations at 20 breaths/minute, and a temperature of 37.4°C. Review of systems

---

is negative except as noted above. On neurologic examination, C.B. is alert and her speech is fluent, but slurred. Her cranial nerves examination reveals sixth nerve palsy, and C.B. cannot abduct the right eye on rightward gaze; her visual fields are full. Her tongue and palate are at midline and there is no facial asymmetry. Her motor examination reveals normal tone and strength; her sensory examination is intact to light touch, pinprick, vibration, and position sense. Her finger-to-nose, rapid alternating movements, heel-to-shin, and gait are all normal. On MRI, C.B. has two gadolinium-enhancing lesions in the right mid-pons. Examination of her CSF reveals the following:

Red blood cells, 0
White blood cells, 0
Protein, 24 mg/dL
Glucose, 60 mg/dL

Her CSF is positive for oligoclonal bands, and IgG synthesis rate is 4.3 mg/24 hours (normal less than 3.3

mg/24 hours). Her current medications include a multivitamin one by mouth (PO) every morning, loratadine 10 mg PO every morning, and levonorgestrel-releasing intrauterine system.

What risk factors, signs, and symptoms suggestive of MS are present in C.B.? How do her MRI and CSF findings support or refute a diagnosis of MS?

C.B. has several epidemiologic factors associated with MS (see Table 57-1): She is 32 years old, consistent with onset between the ages of 20 and 50 years; she is female—women are 2 to 3 times more likely to develop MS than men—and she is of northern European ancestry, which also increases her risk of MS. Her symptoms and physical examination findings are consistent with a demyelinating event in the pons area of the brainstem. On MRI, C.B. has two active (gadolinium-enhancing) lesions in this area. This finding on the MRI is abnormal, and gadolinium-enhancing lesions are found commonly in patients with MS. Additionally, her CSF examination on lumbar puncture shows the presence of oligoclonal bands and an increased rate of IgG synthesis. These findings are also consistent with a diagnosis of MS. Although the combined evidence from her history, examination, and CSF and MRI studies make the eventual diagnosis of MS very likely, they do not demonstrate dissemination in space and time. To show dissemination in time, an additional clinical event or another MRI showing a new lesion would be necessary. To show dissemination in space, another clinical event affecting another part of the body or another MRI showing lesions in a different area of the brain would be necessary.[70] At the present time, C.B. would be diagnosed as having CIS.

CASE 57-1, QUESTION 2: Should C.B. begin treatment at this time? If so, what treatment(s) would be appropriate?

Most of the interferon β preparations, glatiramer acetate, and teriflunomide have demonstrated reduced development of MS if taken after the identification of CIS (Table 57-5).[146–150] It should be noted that the subcutaneous administration of interferon β-1a for CIS was less frequent than the usual treatment regimen of 3 times weekly.[149] This may account for the lower response rate seen in the trial with that regimen compared with the other treatments in Table 57-5.[149] C.B. should be educated on the risk of developing clinically definite MS, and she should begin therapy with one of these therapies. There is no evidence on which to base the choice of therapy; commonly the prescriber will have a preference based on discussion with the patient.

CASE 57-1, QUESTION 3: C.B. is started on glatiramer acetate 20 mg subcutaneously daily. How should C.B. be counseled regarding the injection of glatiramer acetate and the potential adverse effects of this treatment? How can she help alleviate or avoid these adverse effects? What monitoring is required?

Glatiramer acetate is supplied as a single-use, prefilled syringe. In general, the recommended administration techniques are similar to those used for other subcutaneously administered products, and the important counseling points are summarized in Table 57-6. The administration technique is slightly different for the intramuscular injection. There are product-specific differences in dose preparation for which it is important to consult the product information. C.B. should be instructed on administration technique, and it is recommended that the first injection be self-administered under the supervision of a healthcare professional.

Glatiramer acetate is initiated at a dose of 20 mg subcutaneously daily. No dosage titration is required. However, for interferon β products, a product-specific titration schedule is recommended to minimize flu-like symptoms.[79–82]

Common adverse effects of glatiramer acetate are injection site reactions and post-injection systemic reactions.[152] Injection site reactions with glatiramer acetate include hemorrhage, hypersensitivity, inflammation, mass, pain, edema, and atrophy at the injection sites. Rarely, necrosis at the injection site can develop. Lipoatrophy may be seen in up to 45% of patients with longer-term use.[153] Acute injection site reactions may be reduced by applying warm compresses or ice to the injection site before injection, warming the medication to room temperature before injection, and ensuring that the needle completely penetrates the skin during injection.[154,155] Symptoms of post-injection systemic reactions include facial flushing, chest tightness, dyspnea, palpitations, tachycardia, and anxiety.[151] Approximately 16% of patients experience this reaction. When this reaction occurs, its onset is within seconds to minutes after injection, and it may last up to 30 minutes.[152] No specific treatment is recommended for post-injection systemic reactions to glatiramer acetate.

Table 57-5

Development of Clinically Definite Multiple Sclerosis with Therapy Compared to Placebo

		Development of Clinically Definite MS	
Clinical Study	**Treatment**	**Active Treatment (%)**	**Placebo (%)**
CHAMPS[146]	Interferon β-1a 30 mcg IM weekly	20	38
ETOMS[147]	Interferon β-1a 22 mcg subcutaneously weekly	34	45
BENEFIT[148]	Interferon β-1b 250 mcg subcutaneously every other day	28	45
PreCISe[149]	Glatiramer acetate 20 mg subcutaneously daily	25	43
TOPIC[150]	Teriflunomide 7 mg PO daily Teriflunomide 14 mg PO daily	19 18	28

IM, intramuscular; MS, multiple sclerosis; PO, orally.

Table 57-6

Patient Counseling Points for Interferon β and Glatiramer Acetate Products[79–82,151]

For all products:
Use clean technique—wash hands with soap and water, clean injection site with an alcohol swab, do not touch site or needle tip to other surfaces or with fingers.
Choose an appropriate site: For subcutaneous injection—fleshy part of upper back, arm, front of thighs, lower abdomen, fleshy area of upper hip. For intramuscular injection—front of thigh, side of thigh, upper arm.
Rotate between injection sites to avoid overuse of any one site.
Examine the reconstituted product for particles, cloudiness, or color changes. The products should be colorless to light yellow.
For subcutaneous injection—pinch up a fold of skin between index finger and thumb for the injection. For intramuscular injection—stretch the skin between index finger and thumb for the injection.
Insert the needle at a 90 degrees angle to the skin.
Release the skin.
Steadily push down on the plunger until all of the medicine is injected.
Pull needle straight out of skin and dispose of it in a hard-walled plastic container.

Adverse effects are fairly common with interferon β; they include leukopenia (36%–86%), injection site reaction (6%–92%) and necrosis (3%–6%), flulike symptoms (49%–57%), breakthrough menstrual bleeding (28%), and increased liver function tests (12%–27%).[79–82,156] Depression and suicide are seen in patients treated with the β interferons; however, it is difficult to distinguish the independent contribution of interferon from any possible concomitant effects of MS itself.[157–159]

Flu-like reactions include the symptoms of fever, chills, myalgia, malaise, and sweating, and they occur in about half of patients who are initiated on an interferon β.[78] Symptoms usually begin 3 to 6 hours after administration and last approximately 24 hours. Female patients and those with lower body mass index may have more severe flu-like symptoms.[156] Most patients find that these symptoms decrease with time, with only 10% of patients reporting flu-like symptoms after 1 year of therapy.[78] Helpful tips for patients to reduce flu-like symptoms include administering the injections at night to sleep through the time of peak symptoms, taking ibuprofen or acetaminophen before and every 4 to 6 hours as needed after the injection, and gradual titration to full dose.[156],[160]

Injection site reactions vary from 92% with some subcutaneous preparations of interferon β to 6% with the intramuscular preparation.[79–82] These symptoms are similar to those seen with glatiramer acetate except that lipoatrophy is not seen with interferon β. Women appear to be more likely to experience injection site reactions than men.[156] Strategies to reduce injection site reactions include injecting the drug in areas with more subcutaneous fat (abdomen or buttocks), rotating injection sites, using an auto-injection device, icing the site after injection, and using a vitamin K cream on the site.[156],[161–164]

Table 57-7

Patient Characteristics and Other Factors Associated with Reduced Adherence to β Interferons or Glatiramer Acetate[166–168]

Secondary-progressive multiple sclerosis	**Younger age**
Female sex	Cognitive impairment
Depression	Perceived lack of efficacy
Unrealistic expectations	Adverse effects
Inconvenience	Needle phobia
Lifestyle or economic instability	Lack of family or other support

General monitoring recommendations for both interferon β and glatiramer acetate include observation of injection sites for infection, necrosis, and atrophy. Specifically for the β interferons, complete blood counts and liver function tests are monitored.[79–82] The frequency of monitoring is not specified in product literature, but a reasonable approach would be at baseline and 1 to 3 months after initiation and then every 6 to 12 months during continuation of therapy. Additionally, patients should be monitored for signs or symptoms of depression. Therefore, the specific counseling and monitoring plan needed for C.B. is instruction in self-injection technique for the subcutaneous injection and discussion of injection site reactions, including their prevention and monitoring, and post-injection systemic reactions. C.B. should also be counseled regarding the value of ongoing clinical monitoring (for efficacy, injection site reactions, and post-injection reactions) during glatiramer acetate therapy.

CASE 57-1, QUESTION 4: Six months later, C.B. returns for an appointment with her neurologist. During the discussion, she states that she is not having any problems with injection technique or adverse effects, but she reveals that she is only using the glatiramer acetate 3 or 4 times a week instead of the daily injection schedule that was prescribed. When questioned, she states, “I just don’t know that it’s doing anything.” How might C.B.’s neurologist deal with this adherence problem?

Adherence is often poor with self-injection of interferons and glatiramer acetate; over 2 to 5 years, only 60% to 76% of patients adhere to therapy.[165] Patient characteristics and other factors that have been associated with poor adherence are listed in Table 57-7.[166–168] In one study, self-efficacy and belief that the medicine would have benefit were strong predictors of adherence, whereas cognitive difficulties, occurrence of adverse effects, depression, more disability, and poor quality of life predicted nonadherence.[169] Adherent patients have a lower risk of relapses, fewer emergency department visits, and fewer hospitalizations.[170]

For C.B., it appears that she has perceived lack of efficacy for the glatiramer acetate; however, other factors associated with nonadherence should be sought and discussed with her. For an individual patient, it is impossible to know what the course of disease would be without treatment; thus, many patients believe that the medicine is not having a positive impact. Particularly for a patient with CIS who does not have ongoing symptoms, embarking on a lifelong therapy can be challenging. Additionally, there is no immediate feedback to the patient that the medication is having an effect, in contrast to some other diseases such as diabetes in which a fingerstick blood glucose measurement provides positive reinforcement.[166] Some evidence suggests that patients would prefer not to take a treatment that causes significant adverse effects until the symptoms experienced from their MS are worse than the perceived adverse effects.[171] Strategies that may improve adherence include establishing a good patient–healthcare provider relationship, patient education and periodic reinforcement, management of adverse effects, involving care partners, and treating depression.[166]

CASE 57-1, QUESTION 5: After re-education and frank discussion, C.B.’s adherence improves, and she does well for a year on glatiramer acetate therapy. However, a routine monitoring MRI scan shows a new gadolinium-enhancing lesion on her right optic nerve. Additionally, a new non-enhancing lesion is apparent on the MRI scan. Does this new information change her diagnosis and treatment?

With these new MRI lesions, the “separation in space and time” criteria for the diagnosis of MS have been met. Thus, C.B. now would be diagnosed with MS. Given her history, it would appear that she has relapsing-remitting MS. To guide the clinician in choosing the most efficacious therapy, there are data from several clinical trials that directly compare first-line therapies (Table 57-8).[76],[89],[172–177] From the data available, it appears that interferon β-1a intramuscularly once weekly is less effective than the other first-line treatments. Otherwise, the medicines are roughly equivalent for treatment of relapsing-remitting MS. A recently proposed treatment algorithm suggests that patients who present with relapsing-remitting MS should receive dimethyl fumarate, glatiramer acetate, interferon β, or teriflunomide as a first-line therapy. Should disease activity be detected, patients could rotate to another first-line therapy or move to a second-line therapy of natalizumab, fingolimod, or alemtuzumab.[178]

Table 57-8

Clinical Trials Directly Comparing Active Treatments

Trial	Treatments	Results
First-line Therapies		

INCOMIN[172]	Interferon β-1b 250 mcg subcutaneously every other day vs. interferon β-1a 30 mcg IM weekly	Compared with interferon β-1a-treated patients, more interferon β-1b-treated patients were relapse-free (51% vs. 36%), there were fewer mean relapses (0.38% vs. 0.5%), and fewer patients progressing 1 point on the EDSS (13% vs. 30%) after 2 years.
EVIDENCE[173]	Interferon β-1a subcutaneously 44 mcg 3 times weekly vs. interferon β-1a 30 mcg IM weekly	Compared with interferon β-1a IM-treated patients, interferon β-1a subcutaneously treated patients had fewer mean relapses (0.29% vs. 0.4%) and fewer lesions on MRI after 24 weeks.
REGARD[174]	Interferon β-1a 44 mcg subcutaneously 3 times weekly vs. glatiramer acetate 20 mg subcutaneously daily	No significant differences in time to first relapse or MRI changes.
BEYOND[175]	Interferon β-1b 250 mcg subcutaneous every other day vs. interferon β-1b 500 mcg subcutaneous every other day vs. glatiramer acetate 20 mg subcutaneous daily	No differences in relapse rate, EDSS progression, or MRI lesions.
CONFIRM[89]	Dimethyl fumarate 240 mg PO twice daily vs. dimethyl fumarate 240 mg PO 3 times daily vs. glatiramer acetate 20 mg subcutaneous daily vs. placebo	Compared to placebo, all active therapies reduced annualized relapse rates (0.22, 0.20, 0.29 vs. 0.40), EDSS progression, and MRI lesions. No differences between dimethyl fumarate 240 mg twice daily and glatiramer for any outcome except for one type of MRI lesion.
TENERE[176]	Teriflunomide 7 mg PO daily vs. teriflunomide 14 mg PO daily vs. interferon β-1a 44 mcg subcutaneous 3 times weekly	No differences in relapse rate, treatment failure
Second-line Therapies		
CARE-MS I[76]	Alemtuzumab 12 mg IV daily for 5 days, then 12 mg IV daily for 3 days 12 months later vs. interferon β-1a 44 mcg subcutaneous 3 times weekly	More patients taking alemtuzumab were relapse-free (78%) at 2 years than the interferon group (59%). Fewer patients taking alemtuzumab had disease progression (8% vs. 11%)
CARE-MS II[177]	Alemtuzumab 12 mg IV daily for 5 days, then 12 mg IV daily for 3 days 12 months later vs. interferon β-1a 44 mcg subcutaneous 3 times weekly	More patients taking alemtuzumab were relapse-free (65.4%) at 2 years than the interferon group (46.7%). Fewer patients taking alemtuzumab had disease progression (12.71% vs. 21.13%). Fewer patients taking alemtuzumab had new MRI lesions (9% vs. 23%).

EDSS, Expanded Disability Status Scale; IM, intramuscular; MRI, magnetic resonance imaging; PO, orally; IV, intravenous.

CASE 57-1, QUESTION 6: C.B. admits that she disliked giving herself daily injections and began therapy with dimethyl fumarate delayed-release 120 mg PO twice daily for 7 days, then 240 mg PO twice daily thereafter. What counseling should she receive regarding the adverse effects of this medication?

Dimethyl fumarate commonly causes flushing and gastrointestinal (GI) adverse effects; it has been formulated as a delayed-release product to help with these problems. Flushing occurs in about 30% to 38% of patients taking dimethyl fumarate in clinical trials.[89],[179] The GI adverse effects include diarrhea 13%, nausea 11%, and upper abdominal pain 10%.[89],[179] Taking doses with food helps decrease both of these types of adverse effects. In a small study specifically examining flushing and GI effects, the incidence of flushing was much higher, up to 98% in some groups, but decreased somewhat with continued use. Each event lasted between 1 to 2 hours. Aspirin 325 mg taken 30 minutes prior to the dose decreases the incidence of flushing by about 14%. The subjects also had much higher incidences of GI effects, between 79% and 81%, falling to 53% to 61% during the second month of use. GI event onset was a median time of 2 weeks. Aspirin had no effect on GI symptoms.[180] Metoclopramide, ondansetron, dromperidone, antacids, H_2-receptor antagonists, proton pump inhibitors, and antidiarrheals have been recommended to combat the GI symptoms, and antihistamines have been used for flushing but no testing of these approaches has been performed.[181] Lyphopenia occurs in about 2% of patients taking dimethyl fumarate; however, mean lymphocyte count decreases by about 30% in the first year of treatment and then stabilizes. Patients should have a complete blood count at baseline and then annually.[182]

C.B. should be counseled to take her doses with food. Because it is a delayed-release product, she should swallow the capsules whole. If she experiences flushing, aspirin 325 mg PO 30 minutes prior to dosing could be recommended. If she experiences GI problems, those could be treated symptomatically.[182]

CASE 57-1, QUESTION 7: C.B. continued on therapy with dimethyl fumarate. However, 1 year later, she has experienced one relapse and is currently hospitalized with another. She has been adherent to therapy. Her MRI shows several new, gadolinium-enhancing lesions. What therapy should be recommended for acute treatment of C.B.'s current relapse? Would you change her maintenance therapy at this time?

Corticosteroids should be used to decrease the time to recover from acute relapses. The most commonly used regimen is 500 to 1,000 mg intravenous methylprednisolone daily for 3 to 5 days with or without a subsequent regimen of tapering dose oral steroids for 1 to 3 weeks.[183] Comparison of oral and intravenous corticosteroid treatment shows that there are no major differences in clinical outcomes, and both treatments appear to be equally effective and safe.[72] The recommended oral corticosteroid regimen is prednisone 1,250 mg daily every other day for five doses.[184] Some investigators have attempted to use corticosteroids on a chronic basis, giving pulse doses of one or several days monthly; however, this type of regimen does not affect disability progression and should not be recommended.[183],[185] Because C.B. is already hospitalized, she should receive methylprednisolone 1,000 mg intravenously daily for 3 days. If she were an outpatient, either intravenous or oral steroid therapy could be recommended, but an oral corticosteroid regimen would be more convenient.

As MS therapies become more effective, tolerance for relapses has decreased. No evidence of disease activity (NEDA) is a composite measure that indicates that there are: (1) no new or enlarging T2-weighted lesions on MRI; (2) no new gadolinium-enhancing lesions on MRI; (3) no relapses; and (4) no progression on EDSS scores over a period of time.[186] An expert panel was convened to help further clarify this classification of NEDA. This group developed a multiple sclerosis decision model (MSDM) which takes into consideration the domains of relapses, progression, neuropsychology factors, and MRI findings.[187] Points are assigned for each of these domains based on assessments, and users are guided to maintain therapy, closely monitor, or change therapy. However, a number of assessments are required to assign the points which may not be practical in many clinic settings. Percentages of patients in clinical trials achieving NEDA status are between 28% and 42% over the first 2 years of therapy; however, this number appears to drop to around 8% after 7 years in one cohort.[188]

It appears that C.B. is failing treatment with dimethyl fumarate because she has experienced two relapses within approximately 1 year and has substantial new lesion formation on MRI; there are several alternatives at this point. C.B. could change to another first-line therapy (β interferon, or teriflunomide) or she could begin therapy with a second-line agent: mitoxantrone, natalizumab, or fingolimod. There are direct comparator studies of first- and second-line agents (Table 57-8). Additionally, an observational study has addressed the question of the efficacy of the second-line therapies, natalizumab and fingolimod.[189] Patients who had relapse activity on first-line injectable therapies were switched to either natalizumab or fingolimod. The annualized relapse rate for those changed to natalizumab was reduced from 1.5 to 0.2 whereas the rate for those changed to fingolimod was reduced from 1.5 to 0.4 ($p = 0.02$). A careful discussion of the potential risks and benefits of each possible treatment will ensure that the patient is well educated on the options and that an appropriate selection is made.

CASE 57-1, QUESTION 8: After lengthy discussion, C.B. elects to discontinue dimethyl fumarate therapy and start fingolimod 0.5 mg PO daily. How should C.B. be counseled regarding the potential benefits and adverse effects of fingolimod? What monitoring will be necessary?

In studies of fingolimod, 70.4% of patients remained relapse-free for 2 years compared with 45.6% for those treated with placebo. At 1 year, 82.6% of fingolimod-treated patients were relapse-free compared with 69.3% of those treated with interferon β-1a intramuscularly. The annualized relapse rate was 0.16/year for fingolimod, 0.40/year for placebo, and 0.33/year for interferon β-1a intramuscularly.[91],[92] C.B. should expect good suppression of her MS with fingolimod treatment.

Because S1P receptors (the targets of fingolimod therapy) are not confined to lymphocytes, adverse effects of fingolimod may affect other body organs and tissues. For example, a transient, dose-dependent reduction in heart rate can occur within 1 hour after the first fingolimod dose (bradycardia in 1.3%); first- and second-degree atrioventricular block can also occur (0.1% and 0.2%, respectively).[91],[190] Patients with pre-existing sinus bradycardia or heart block without pacemakers should not be given fingolimod. Other adverse effects include macular edema and a reduction in forced vital capacity.[91] Because the mechanism of action of fingolimod is to prevent lymphocytes from circulating, there is a reduction in peripheral blood lymphocytes and an increase in infections and, possibly, cancers.[91] This reduction in peripheral blood lymphocytes is reversible within 4 to 8 weeks of discontinuation of fingolimod.[49] Fingolimod does not inhibit humoral immunity to infections.[49] Progressive multifocal leukoencephalopathy (PML) has been reported in patients taking fingolimod.[191] PML is caused by JC DNA polyomavirus (JCV) reactivation. JCV then causes an infection of oligodendrocytes that is often fatal or causes permanent disability.[4] Dormant JCV infection is relatively common, with 50% to 86% of adults having antibodies to JCV. When a patient is immunosuppressed, JCV may become reactivated.[192] PML is rapidly progressive and has a mortality rate of approximately 50%.[193] Symptoms of PML include neurobehavioral, motor, language, and cognitive changes; seizures; vision changes; hemiparesis; and tremor.[194],[195] Notably, all of these symptoms could be mistaken for an MS relapse.

Table 57-9

Baseline Testing and Monitoring Associated with Fingolimod[196]

Baseline
■ Varicella zoster immunity evaluation and vaccination, if needed
■ Ophthalmology evaluation for macular edema
■ Dermatologic evaluation for melanomas
■ Forced expiratory volume in 1 second (FEV_1) or full pulmonary function testing, if patient has history of asthm or chronic obstructive pulmonary disease
■ Pulse and blood pressure
■ Complete blood count
■ Liver function tests
Monitoring
■ Observe in clinical area for 6 hours after initial dose with monitoring of blood pressure and pulse
■ Ophthalmology evaluation at 4 months and as needed thereafter
■ Complete blood count every 6 months
■ Liver function tests every 6 months
■ Dermatologic evaluation as needed

- FEV_1 as needed

Increases in liver enzymes (transaminase and bilirubin) have also been observed.[91],[92] Because fingolimod has a long half-life of 9 to 10 days, its pharmacologic effects will still be present for up to 2 months after therapy is discontinued.[196] Baseline testing and continued monitoring recommended with the use of fingolimod is summarized in Table 57-9. Fingolimod should be given as monotherapy, and the patient should not have had a relapse or have been treated with corticosteroids within 30 days of starting treatment. If patients do not have an existing history of varicella zoster infection or vaccination, vaccination evaluation should be undertaken.[196] Rates of varicella infections are between 7 and 11/1,000 patient-years.[197] C.B. should wait for 30 days after her relapse and any corticosteroid treatment before starting fingolimod. During this time, she can have baseline testing before starting treatment. She should be educated on potential adverse effects and the long-lasting pharmacologic effects of fingolimod that may persist for up to 2 months after therapy is discontinued.

CASE 57-1, QUESTION 9: C.B. is appropriately started on fingolimod and does very well with visits to the neurologist every 6 months. When she is seen 2 years later, she informs her care providers that she is considering having another child. How should C.B. be counseled regarding fingolimod therapy during pregnancy?

It is well documented that the rate of relapses for women with MS decreases during pregnancy, increases in the first 3 months after delivery, then returns to the pre-pregnancy rate.[198] No treatment for MS is recommended for use during pregnancy, and some therapies, such as mitoxantrone, require pregnancy tests before each infusion. However, there are limited data regarding the exposure of fetuses to some of the treatments for MS when given during early pregnancy. No increase in spontaneous abortions or stillbirths was seen with glatiramer acetate or β interferons.[199–201] However, very few of these exposures were for the full term of pregnancy. A report of 66 pregnancies in women taking fingolimod found fetal abnormalities in 7.6%. In all of these cases, the exposure was in the first trimester.[202] Pregnancy is contraindicated during treatment with teriflunomide, with contraception required for both women and men.[203] Eighty-nine pregnancies (70 in women exposed to teriflunomide and 19 in partners of men exposed to teriflunomide) were reported during clinical trials. Of these, 42 healthy live births, 31 induced abortions, and 14 spontaneous abortions were reported. It should be noted that in almost all cases, teriflunomide was stopped and accelerated elimination procedures were undertaken as soon as the pregnancy was known to minimize fetal exposure.[204] Alemtuzumab is also contraindicated during pregnancy. Women should use adequate contraceptive measures during treatment and for 4 months following treatment. Alemtuzumab can cause thyroid disorders which, during pregnancy, can have serious adverse effects on the fetus.[205]

In general, MS therapy should be discontinued before conception. In the case of C.B., she should be advised that she would need to discontinue fingolimod at least 2 months before conception and stay off the medication while pregnant. It is not known whether fingolimod is excreted into the breast milk of nursing women.[202] Because of the potential adverse effects of fingolimod on an infant's immune system, she should be advised either to not breast-feed or to abstain from taking fingolimod during nursing.

CASE 57-1, QUESTION 10: C.B. discontinued fingolimod, conceived approximately 4 months later, and delivered a healthy male child after a normal gestation and labor. She experienced a relapse of MS 2 months after delivery, discontinued nursing, and was treated with corticosteroids. Two months after the relapse and treatment, she returns to the neurology clinic for a follow-up appointment. She states that she is ready to restart fingolimod therapy at this time. She states that she is often very tired and feels that "she can't continue." However, she admits that this feeling may also be related to being a new mother. She states that her husband and daughter help significantly with care of the infant. She has noticed some jerkiness in her gait, and she states that sometimes her toes will contract toward her head involuntarily. Her neurologic examination shows spasticity in her lower extremities. What treatments would be appropriate for management of C.B.'s spasticity? How should her fatigue be addressed?

Nonpharmacologic therapy such as stretching may help with C.B.'s spasticity. Her symptoms are more generalized (involving the lower extremities) than localized, so systemic therapy may be more beneficial than localized therapy such as splinting or botulinum toxin injections (therapies that might be considered if only her toes were involved).[59],[131] Systemic therapies that may relieve spasticity include baclofen and tizanidine; because both agents appear to be equally effective, neither agent is preferred over the other for C.B.

Although fatigue is a common problem when caring for infants, C.B. also may be experiencing fatigue related to her MS. She would likely benefit from nonpharmacologic therapy such as avoiding sleep deprivation to the extent possible and concentrating her infant care during the morning hours, enlisting more assistance in the afternoon and evening. She should also be assessed for any symptoms of depression.[59]

CASE 57-2

QUESTION 1: N.R. is a 47-year-old woman who was diagnosed with relapsing-remitting MS 5 years ago. She has been taking interferon β-1b 250 mcg subcutaneously every other day since diagnosis. For the first 4 years, she did very well with only one relapse. However, in the past year, she has sustained two relapses, and she feels that her treatment is not working as well as it did in the past. Her neurologist sends a blood specimen for neutralizing antibody assay with a result of 160 neutralizing units/mL (reported as high by the laboratory). How might this result assist in the recommendation of future therapy for N.R.?

Neutralizing antibodies develop in many patients given therapy for MS, including β interferons, natalizumab, and alemtuzumab. Neutralizing antibodies are seen in up to 44% of patients given interferon β.[78],[93] Fewer patients given interferon β-1a intramuscularly once weekly develop them than those given interferon β-1a subcutaneously 3 times weekly or interferon β-1b subcutaneously every other day.[93] For patients with persistently high antibody titers, their relapse rates are also higher.[93] With time, neutralizing antibodies often disappear.[87]

Despite these observations, the indications for neutralizing antibody testing and the interpretation of test results are areas of ongoing controversy. The Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology has issued the following statements regarding neutralizing antibodies to interferon β: (a) treatment with interferon β is associated with the production of neutralizing antibodies; (b) it is probable that neutralizing antibodies, especially in persistently high titers, are associated with a reduction in the radiographic and clinical effectiveness of treatment; (c) it is probable that the rate of neutralizing antibody production is less with interferon β-1a compared with interferon β-1b treatment; (d) it is probable that the seroprevalence of neutralizing antibodies is affected by one or more of the following: formulation, dose, route of administration, or frequency of administration of interferon β; and (e) there is insufficient information on the utilization of neutralizing antibody testing to provide specific recommendations regarding the indications for testing or interpretation of antibody titer results.[206]

A panel of MS and neutralizing antibody experts was convened in 2009 to develop practical recommendations. Some of their findings included are as follows: (a) Persistently high titers might provide sufficient guidance to suggest stopping therapy in a patient; however, with low or intermediate titers, additional information might be needed to make a decision regarding therapy continuation; (b) different interferon β products are associated with different rates of antibody formation; chemical formulation, route of administration, and frequency of dosing appear to have an effect; and different formulations of the same molecule may result in different immunogenicity; and (c) to minimize assay variability, antibody measurements should be done in laboratories that have fulfilled the criteria for validation of neutralizing antibody assays, and interferon β-1a should be used in the assays to standardize the assays.[207] Thus, there is continued discussion about the appropriate use of neutralizing antibody assays for β interferons.

Antibodies also form to therapies for MS other than the β interferons. Up to 95% of patients treated with glatiramer acetate have antibodies, but they do not appear to change the efficacy of glatiramer acetate.[152],[208] Antibodies may develop to natalizumab and may affect treatment efficacy or increase the likelihood of natalizumab infusion reactions. Many patients who express antibodies to natalizumab do so within the first 6 months of treatment, but these antibodies often disappear with continued treatment. Antibodies to natalizumab are more likely to persist if they develop more than 6 months after treatment initiation.[194] High antibody titers are associated with increased rates of relapse.[209] Neutralizing antibodies have been detected with alemtuzumab, but they do not appear to affect efficacy.[177]

N.R. has a high titer of neutralizing antibodies, and they appear to be associated with a decline in efficacy of her interferon β-1b. Therefore, it would seem appropriate to change therapy at this time. Options would include glatiramer acetate, dimethyl fumarate, teriflunomide, alemtuzumab, mitoxantrone, natalizumab, or fingolimod. Because of the potential for cross-reactivity of the neutralizing antibodies to other β interferons, a change to another β interferon product would not be expected to provide benefit.

CASE 57-2, QUESTION 2: N.R.'s interferon β-1b therapy was discontinued, and she was begun on teriflunomide 14 mg PO daily. What monitoring will be required while taking this medicine?

Elevated ALT, alopecia, and diarrhea were seen in 10% to 20% of patients in clinical trials and more commonly in patients treated with teriflunomide than with placebo.[203] White blood cell counts decrease by about 15% and platelets by about 10% during the first 6 weeks of teriflunomide treatment, and remain low throughout the treatment. A CBC is recommended at baseline.[203] Because of the immunosuppression seen, patients should be monitored for infection, and patients should not receive live virus vaccines while under the effects of teriflunomide.[203] Modest increases in blood pressure were also observed. Other required monitoring includes baseline liver enzymes and bilirubin, blood pressure, and screening for latent tuberculosis infection. The monitoring of ALT should occur monthly for the first 6 months of therapy and periodically thereafter.[203] Teriflunomide rarely causes the serious adverse effects of peripheral neuropathy, acute renal failure, hyperkalemia, and bone marrow suppression.[101] Serious adverse effects are not reported with teriflunomide, but those seen with the parent drug leflunomide are Stevens–Johnson syndrome, interstitial lung disease, and hepatotoxicity.[203] Teriflunomide has a very long half-life of approximately 18 days.[203] Because of this, it can take up to 3 months to achieve steadystate serum concentrations and a proportionally long time to eliminate the medicine (8–24 months). In situations requiring rapid elimination of teriflunomide (e.g., serious adverse effects, desired pregnancy), accelerated elimination procedures are recommended. The recommended accelerated elimination procedures are administration of cholestyramine 8 g every 8 hours for 11 days or administration of activated charcoal powder 50 g every 12 hours for 11 days. Verification of elimination should be undertaken by two teriflunomide serum concentrations of <0.02 mcg/mL taken 2 weeks apart.[203]

Prior to N.R. starting teriflunomide, her immunization status should be carefully checked and she should be screened for tuberculosis. If necessary, her immunizations should be updated and any infectious diseases should be completely treated before starting therapy. She should have a baseline CBC, liver enzymes, bilirubin, and blood pressure. Monthly for the first 6 months, she should have blood drawn for ALT. This would also be an opportune time to check blood pressure and screen for signs of infection.

CASE 57-2, QUESTION 3: N.R. successfully began teriflunomide and continued without adverse effects for 1 year. At her annual MRI visit, however, five new lesions were seen in her brain. She continued for another 6 months and had a follow-up MRI with three additional lesions detected. In discussion with her neurologist, she decided to change therapy. Alemtuzumab, mitoxantrone and natalizumab are considered as therapy alternatives for N.R. How should N.R. be counseled regarding the potential adverse effects and monitoring for these agents?

Common adverse effects of mitoxantrone include nausea, menstrual abnormalities, alopecia, upper respiratory and urinary tract infections, neutropenia, and a temporary change to blue color in the urine and sclera.[210] Dose-related cardiotoxicity occurs with mitoxantrone use, requiring an estimation of left ventricular ejection fraction before each dose.[211] The dose of mitoxantrone for MS is 12 mg/m^2 given as a 5- to 15-minute intravenous infusion every 3 months.[211] Cardiotoxicity limits the lifetime dose of mitoxantrone to 140 mg/m^2 or approximately 3 years of therapy. The most common cardiotoxic effects are cardiomyopathy, decreased left ventricular ejection fraction, and irreversible congestive heart failure.[210] Approximately 12% of patients experience decreased left ventricular ejection fraction, and 0.4% exhibit congestive heart failure.[212] Treatment-related acute leukemia may occur in 0.81% of mitoxantrone-treated patients. Most cases of leukemia present during the first few years of mitoxantrone therapy, and the development of leukemia may be dose related.[212] It appears that limiting the cumulative dose of mitoxantrone to <60 mg/m^2 may reduce the risk of leukemia.[213] Recommended monitoring for patients taking mitoxantrone is presented in Table 57-10. It should be noted that adherence to mitoxantrone monitoring recommendations is low. In a review of 548 patients, 78% had complete blood counts, 54% had liver function tests, 18% had left ventricular ejection fraction determinations, and 10% of women had pregnancy tests before each infusion.[214] Because of the cardiac and leukemia concerns, mitoxantrone is rarely used for MS.

Table 57-10

Monitoring Required for Mitoxantrone Use[211]

Baseline and Before Each Dose
■ Left ventricular ejection fraction ■ Complete blood count ■ Liver function tests ■ Pregnancy test, in women
Ongoing
■ Left ventricular ejection fraction yearly to monitor for late development of cardiotoxicity

Adverse effects of natalizumab include fatigue, liver dysfunction, infections, hypersensitivity reactions, and infusion-related reactions.[215] Hypersensitivity reactions are IgE-mediated and occur within 2 hours of the start of the infusion. Patients who exhibit HLA-DRB1*13 or HLA-DRB*14 are more likely to have hypersensitivity reactions.[216] Genotyping may be helpful to identify these patients prior to natalizumab prescribing. Symptoms include urticaria, dyspnea, and circulatory, and vital sign changes. If these symptoms occur, the infusion should be discontinued.[194] Hypersensitivity reactions should be distinguished from infusion-related reactions. These latter reactions are non-allergic and include symptoms of headache, dizziness, fatigue, nausea, sweats, and rigors. If this type of reaction occurs, there is no need to discontinue therapy; the patient can be pretreated with histamine type 1 and 2 receptor antagonists and acetaminophen.[194] Three cases of PML caused the suspension of natalizumab sales shortly after its introduction.[217] Natalizumab was later reintroduced to the market with a limited distribution system and extensive monitoring requirements.

From 2005 to 2009, 28 cases of PML in natalizumab-treated patients were reported in addition to the three cases reported previously. During that period, approximately 65,000 patients with MS were exposed to natalizumab. However, it appears that PML risk is proportional to the duration of natalizumab exposure; one case is reported per 1,000 patients in those who have received 24 or more infusions.[195] Overall, reporting appears to occur at a rate of one or two per month.[195] Of these 28 cases, only eight have been fatal.[195] This may be due to the heightened sensitivity to clinical changes that may suggest PML and aggressive immune reconstitution with either plasma exchange or immunoabsorption if PML is diagnosed. However, this immune reconstitution can lead to immune reconstitution inflammatory syndrome (IRIS), which is itself life-threatening. IRIS usually presents as an acute worsening of MS symptoms and is treated with high-dose corticosteroids.[195] Several groups have developed recommendations for natalizumab use to reduce the risk of PML (Table 57-11).

Table 57-11

Recommendations for Use of Natalizumab[93,194,215]

Patients Who Should Not Receive Natalizumab

- Immunocompromised
- Active viral hepatitis
- Active malignancy that requires treatment
- Inability to get MRI

Recommendations for Use

- Monotherapy with natalizumab only
- After failure of interferon or glatiramer acetate

- Therapy-free interval of 14 days after interferon or glatiramer acetate, 3 months after azathioprine, or 6 month after mitoxantrone

Baseline Testing

- Clinical neurologic examination
- Human immunodeficiency virus testing
- Complete blood count
- Liver function tests
- MRI with IV contrast

Monitoring

- Neurologic examination at 3 months, 6 months, and then yearly
- MRI with IV contrast at 6 months and then yearly

IV, intravenous; MRI, magnetic resonance imaging.

Several serious adverse effects, infusion reactions, autoimmune conditions, and malignancies, associated with alemtuzumab use have caused the FDA to require a limited distribution program for this agent. Infusion reactions associated with alemtuzumab are triggered by cytokine release, may include rash, fever, headache, itching, nausea, and chills and occur in about 90% of patients; serious reactions occurred in 3% of patients.[74,76,205] Patients should be monitored for 2 hours after each infusion, but reactions may occur later than that time period.[205] Premedication should consist of methylprednisolone 1,000 mg infused immediately before the first infusion and for the first 3 days of each treatment course. Antihistamines and acetaminophen may also be helpful premedications.[205] Autoimmune diseases have been associated with alemtuzumab therapy and may include thyroid disorders (34%), immune thrombocytopenia (2%), and anti-glomerular basement membrane disease (0.3%).[76,177,205] Thyroid disorders have been seen up to 60 months after the initial treatment with alemtuzumab.[177] Of thyroid dysfunction seen, 79% is hyperthyroidism and 21% is hypothyroidism.[218] Patients receiving alemtuzumab had higher rates of some malignancies, including thyroid cancer and melanoma at a rate of 0.3% each.[205] Infections were more common in patients treated with alemtuzumab than those treated with interferon β, including urinary tract infections (17%), herpes virus infections (16%), respiratory infections (16%), and fungal infections (12%).[76,177,205] The herpes virus infections are most common in the month following the infusion and can be significantly reduced by prophylaxis.[74] The recommendation is that patients receive anti-viral prophylaxis for herpetic viral infections starting on the first day of each treatment course and continuing for a minimum of 2 months following treatment or until the $CD4^+$ lymphocyte count is ≥ 200 cells/mcL, whichever occurs later.[205] The dosing of alemtuzumab is unique for MS medicines in that it is a 12 mg/day infusion for 5 days and then an additional 12 mg/day infusion for 3 days 12 months after the first treatment course.[205] No vaccines should be administered during treatment and all should be completed at least 6 weeks prior to treatment, including varicella zoster virus vaccine, if patients have not been vaccinated and do not have a history of infection.[205] Monitoring recommendations can be found in Table 57-12.

Table 57-12

Recommended Monitoring for Use of Alemtuzumab[205]

Test	Monitoring Frequency
CBC with differential	Baseline and monthly for 48 months following the last dose
Serum creatinine	Baseline and monthly for 48 months following the last dose
Urinalysis with urine cell counts	Baseline and monthly for 48 months following the last dose
Thyroid-stimulating hormone	Baseline and every 3 months for 48 months following the last dose
Skin examination	Baseline and yearly
Human papilloma virus	Yearly
Tuberculosis	Baseline

Of these options, N.R. should probably be started on alemtuzumab or natalizumab. Both of these therapies carry substantial adverse effects about which, she will need to be informed. Additionally, she will need to enroll in the restricted distribution systems for the chosen medicine. Another area that requires consideration is that she may be at higher risk for PML or other opportunistic infections when beginning one of these medicines after taking teriflunomide. Conversely, being completely without medicine allows for return or possible "rebound" of disease activity. Possible strategies include undergoing accelerated elimination procedures for the teriflunomide and then: (1) allowing for a washout period during which the patient receives no treatment, (2) providing a monthly regimen of methylprednisolone while allowing for a washout period, or (3) switching directly to another therapy without a washout period.[219] It is not known which of these options is the best for a patient.

CASE 57-2, QUESTION 4: N.R. experiences another relapse while she is considering which therapy to begin. One month after completing corticosteroid treatment for this relapse, she returns to the neurology clinic for a follow-up appointment. N.R. explains that she has been experiencing episodes of uncontrollable laughing. When these episodes first began, she thought they might be an adverse effect of the corticosteroid treatment for her relapse. However, 1 month after stopping corticosteroid treatment, she is still having these episodes. She states that the episodes are very embarrassing, often occurring at inappropriate times such as in movie theaters, at parent–teacher conferences, and in grocery stores. She is diagnosed with pseudobulbar affect. What treatment is available for pseudobulbar affect, and how should N.R. be counseled regarding this treatment?

Dextromethorphan with quinidine is effective for reducing the rate of pseudobulbar affect episodes and was recently FDA-approved for this indication. It is dosed one capsule (dextromethorphan 20 mg/quinidine 10 mg) orally twice daily.[220] Adverse effects related to the dextromethorphan component may include dizziness and the possibility of serotonin syndrome. Adverse effects associated with quinidine are an immune-mediated thrombocytopenia, lupus-like syndrome, hepatotoxicity, dose-dependent QTc interval prolongation, and anticholinergic effects.[220]

There are several drug interactions associated with dextromethorphan–quinidine.[220] It is contraindicated with monoamine oxidase inhibitors, requiring a 14-day washout before starting therapy. Similarly, caution should be exercised when this therapy is used concomitantly with selective serotonin reuptake inhibitors and tricyclic antidepressants. It is contraindicated with drugs that prolong the QT interval and are metabolized by CYP 2D6. Dextromethorphan–quinidine should be used with caution with drugs that inhibit CYP 3A4. Because quinidine inhibits CYP 2D6, dose adjustments for CYP 2D6 substrates are necessary. Quinidine also inhibits P-glycoprotein, requiring caution and perhaps dose adjustments when this treatment is used in combination with digoxin.

Headache

Steven J. Crosby

CORE PRINCIPLES		CHAPTER CASES
1	Migraine, tension-type, and cluster headache are classified as primary headache disorders. Subtle differences in symptomatology and the presence of auxiliary symptoms assist in defining headache type.	Case 58-1 (Questions 1, 2, 3, 6), Case 58-2 (Questions 1, 3), Case 58-4 (Question 1)
2	Virtually all patients who suffer from migraine, tension-type, and cluster headaches are candidates to receive abortive (or symptomatic) medications during an acute attack. Prophylactic treatment may be considered for all primary headache types and is driven by various factors including headache frequency, the level of disability imparted by the headache, and response to acute treatment modalities.	Case 58-1 (Questions 4, 7–10, 11, 12), Case 58-2 (Questions 2, 4, 5), Case 58-4 (Questions 2, 3), Case 58-5 (Questions 1, 2)
3	Triptans are the drugs of choice as migraine-specific treatments for acute episodes. Triptans are effective in managing associated symptoms of migraine (e.g., nausea, photo- and phonophobia). Differences within the class are observed on the basis of pharmacokinetics.	Case 58-1 (Questions 5, 7, 8), Case 58-2 (Question 4, Table 58-1)
4	Evidence supports the use of propranolol, amitriptyline, or topiramate as first-line agents for migraine prophylaxis. The decision to initiate prophylaxis takes into account headache frequency, the impact of attacks on patient functioning, and response to acute treatments. Medical history and adverse effect profile are relevant considerations for specific drug selection.	Case 58-1 (Question 12), Case 58-2 (Question 5)
5	Overuse of symptomatic or abortive agents (including triptans and over-the-counter, combination, and opioid analgesics) can increase the intensity and chronicity of all headache types. To prevent medication overuse headache, use of these agents should be limited to fewer than 10 days/month.	Case 58-3 (Question 1)
6	Cluster headaches are severely painful and short-duration attacks that tend to occur nightly during susceptible periods and then enter remission for a period of months or years. Treatments of choice for abortive treatment must be fast-acting and include subcutaneous sumatriptan, intranasal zolmitriptan, and oxygen inhalation.	Case 58-4 (Questions 1–3)
7	Tension-type headaches (previously known as tension or muscle contraction headaches) usually cause mild-to-moderate discomfort. Conventional analgesics are often appropriate for acute management.	Case 58-5 (Question 1, 2)

Some patients with tension-type headache may require prophylactic treatment, for which amitriptyline, mirtazapine, and venlafaxine have demonstrated efficacy.

EPIDEMIOLOGY AND DESCRIPTION

Prevalence

Previous investigations have determined that migraine prevalence approximates 12%.[1],[2] Survey data obtained from the American Migraine Prevalence and Prevention Study (2004) support the same percentage, as applied to meeting International Classification of Headache Disorders-2 criteria.[2] Across ambulatory care settings, migraine accounts for 0.5% of all encounters, with a majority occurring in primary care settings whereas emergency department (ED) visits approximate 3%,[3] being further stratified within the top 10 causes for ED encounters in the U.S.[4] There is demonstrated variability across both gender and age, with a higher incidence in females,[1–3] and a higher prevalence between 30 and 39 years.[1] Such age- and gender-associated prevalence has been further substantiated in surveillance reviews.[4]

Classification

There is inherent difficulty in evaluating and classifying headache, because this symptom may be attributed to either a physiologic, psychological, or pathologic process, or may be an adverse outcome associated with medications. Because the processes contributing to headache are vast, it is imperative to conduct a comprehensive patient assessment. Broadly categorized, headache is defined as primary or secondary, with the latter typically being attributable to an organic cause. Primary headache is inclusive of migraine, tension headache, and trigeminal cephalalgias, of which cluster headache would be one category. Further, headache associated with physical activity, exposure to exogenous stimuli, or those evolving during the sleep cycle would be categorized as primary.[5] Secondary headache may be attributable to, but not limited to, traumatic injury, vascular or nonvascular cranial pathology, tumor formation (neurofibroma), or an infectious process.[5]

The appropriate classification ultimately speaks to the larger issue of optimal management, via either medical procedures or the initiation of medication. Because secondary headache is associated with a causative component, targeting that cause becomes a principle intervention strategy.

PRIMARY HEADACHE DISORDERS

Migraine

The timeline for the evolution of migraine can often be expressed in terms of minutes. The clinical assessment process for differentiating headache type is dependent upon recognizing general characteristics of migraine and further distinguishing such characteristics from other primary headache forms. An assessment of location can be useful but should not be used as a prime differentiator between headache types because migraine location can be unilateral or bilateral in nature. Patient assessment should include an evaluation of both pain intensity and pain quality, because migraines are commonly described as moderate-to-severe pulsating pain.[5] Migraine duration typically ranges from 4 to 72 hours and may be accompanied by auditory (phonophobia) and light (photophobia) sensitivity, as well as nausea and vomiting.[5,6] These auxiliary symptoms are mediated via the hypothalamus and the chemoreceptor trigger zone (CTZ), indicating diffuse neuroanatomic involvement. The aforementioned features have demonstrated reliable predictive value in migraine diagnosis, as defined by the POUND mnemonic (pulsating, 4–72 hour duration, unilateral nature, nausea or vomiting, disabling effect).[7] The presence of 4 out of the 5 criteria indicates high probability of migraine.[7]

Migraine may be preceded by a constellation of optical or sensory features, defined as an aura. The presence or absence of an aura highlights an important differentiator in migraine diagnosis. International Classification of Headache Disorders criteria indicate a disparity in the number of episodes consistent with a diagnosis of migraine without aura (minimum of five episodes) versus migraine with aura (minimum of two episodes).[5] This criterion is not the only parameter considered, because additional criteria pertaining to headache characteristics also need to be met for an appropriate migraine diagnosis. Auras most often affect vision, with either positive (visual feature) or negative (localized blindness) character.[5] Sensory effects can be characterized similarly as positive (pins and needles description) or negative (loss of sensation or numbness).[5] Aura character that extends beyond the visual and sensory, such as motor or speech irregularity, is linked more toward specialized migraine diagnoses.[5] Patients with suspected migraine should be advised to document aura timing and description, because this information can be valuable for accurate diagnosis.

Patient report of pain location in migraine may be widespread due to the branching of the trigeminal nerve, which facilitates sensory effects across facial regions. Anatomically, the trigeminal nerve features branches of V1, V2, and V3.[8] Branch V1 innervates the scalp, orbital region, and meninges, V2 is directed to the top of the jaw and sinus region, and V3 innervates lower mandibular regions.[8] Additionally, patients may report pain referral to the suboccipital region due to the close proximity between occipital nerves and the spinal nucleus.[8]

Cluster Headache

Cluster headache is characterized within the domain of primary headache disorders. Whereas migraine can be unilateral or bilateral, cluster headache is primarily unilateral involving orbital and/or temporal pain, which can persist for up to 3 hours.[5] Independent of duration, such episodes may occur multiple times during the day.[5] Associated symptoms that occur with high prevalence during cluster headache include lacrimation, rhinorrhea, miosis, ptosis, diaphoresis, and flushing.[5] Preferential incidence of cluster headache occurs in males, but there is similarity to migraine on the basis of age prevalence.

Tension-Type Headache

Tension-type headache is of bilateral character and by comparison to migraine, is often associated with less intense pain without a pulsating quality. An individual's subjective description of pain quality and intensity can be useful in differentiation. Patients may use such terminology as "tightening" to characterize symptoms. The combination of symptoms of photophobia, phonophobia, and nausea/vomiting is not considered to be consistent with the diagnosis of tension headache; however, the individual symptoms of photo- or phonophobia may accompany tension-type headache.[5]

To complete the discussion pertaining to primary headache pathology, the International Headache Society (IHS) defines headache in association with cough, exercise, sexual activity, cold stimuli, and external compression under the umbrella of primary headache disorders.[5]

SECONDARY HEADACHE

Causation is the key principle underlying secondary headache. Such attributable causes include head or neck trauma, cervical vascular dysfunction, nonvascular cranial dysfunction, infection, psychiatric pathology, or substance withdrawal effects.[5] Causation becomes a critically important principle to consider in patient assessment, particularly when headache onset deviates substantially from existing prevalence and epidemiologic data.

Acute Headaches

Acute headaches may be linked to subarachnoid hemorrhage, stroke, meningitis, or intracranial mass (e.g., neurofibroma, abscess, etc.). It is within this clinical context that diagnostic measures of neuroimaging and lumbar puncture are more commonly implemented. Commonalities of headaches associated with such pathology are of severe quality and rapid evolution, perhaps described as the "worst headache" experienced. An increase in intracranial pressure is of particular importance, and recognition of factors that can impact intracranial pressure becomes critical in patient assessment.

Subacute Headaches

Subacute headaches may be a sign of increased intracranial pressure, intracranial mass lesion, temporal arteritis, sinusitis, or trigeminal neuralgia. Trigeminal neuralgia usually occurs after the age of 40 and is more common in women than in men. The pain usually occurs along the second or third divisions of the trigeminal (facial) nerve and lasts only moments. Trigeminal neuralgia is characterized by sudden, intense pain that recurs paroxysmally, often in response to triggers such as talking, chewing, or shaving.

The evaluation of headache pathology should incorporate the consideration of reported prevalence data, patient age, the presence of triggers or aggravating factors, the contribution of past medical history to headache origin, the patient's description and characterization of symptoms and frequency, and any record of self-care interventions employed to manage headache. Evaluating the impact of headache on daily activity and function is a similarly important consideration. A diagnosis may be confirmed on the basis of this information without the need for further laboratory or procedural measures. If objective or subjective information becomes suggestive of a clinical anomaly (e.g., late-age onset of headache, suspected structural anomalies or neural tissue pathology, etc.), a more comprehensive evaluation, inclusive of additional diagnostic measures (e.g., imaging, lumbar puncture), is indicated.

Pathologic Basis

The pathologic picture of headache requires an understanding of vascular physiology and the functions of the trigeminovascular circuit and neuropeptides. Headache involves both peripheral and central pain processing, afferent neuronal excitability, and pain sensitivity of cerebral arteries and venous sinuses.[5,9] The pathology has often been described within the context of interactions between vascular and neurologic systems.[6,10] Muscular tenderness similarly contributes to headache pathology.[9,11] Such an effect is more commonly considered in association with tension headache.

Recent evidence has conferred support for the interplay between vascular and neurologic function. Afferent and efferent fibers of the trigeminovascular circuitry, vasoactive neuropeptides stored within this system, and serotonin (5-HT) maintain significant pathologic importance.[6,12,13] Neuropeptides, such as substance P, neurokinin A, nitric oxide, calcitonin gene-related peptide, and adenylate cyclase-activating peptide, are promoters of neuroinflammation and vessel dilation.[6,13] Recent evidence further suggests an elevation in pro-inflammatory C-reactive protein in migraine sufferers compared to controls.[14] Consequently, therapeutic interventions have focused on modulating the effects of 5-HT with recent efforts directed toward the modulation of neuropeptide function.

Drug Therapy

The primary goal of therapy is the resolution of headache symptoms, most prominently pain, and attenuating disability associated with the headache. Nonpharmacologic recommendations should similarly be paired with therapeutic options. Pharmacologic treatment options can be divided into abortive and prophylactic, the former resolving acute episodes and the latter being administered chronically to reduce the incidence of recurrent headaches. Abortive treatment may sufficiently manage tension-type headache, often negating the need for prophylactic treatment; however, this may be considered when acute treatment is ineffective, overused, or when the headache is chronic or occurring in frequent episodes. Conversely, patients with migraine and cluster headache, while requiring abortive treatment, may commonly also require long-term prophylactic treatment.

Success in managing acute episodes can often be achieved with the use of conventional analgesics or headache-specific medications (e.g., dihydroergotamine, triptans). Medication selection should be based on the patient's prior treatment experience and the level of disability imparted by the headache episode. With regard to prophylactic therapy, evidence supports the use of select antidepressants, anticonvulsants, and antihypertensives. The selection of such agents should be considered within the context of adverse effect profiles and the potential for utility in managing other medical conditions (e.g., prescribing a β-antagonist for migraine prophylaxis in a patient with a history of hypertension). Rational prescribing limits both the potential for polypharmacy and the risk of adverse effects.

MIGRAINE HEADACHE

Migraine is characterized by pain of a throbbing quality with moderate-to-severe intensity and the presence of associated symptoms, including nausea, vomiting, light, and/or auditory sensitivity.[5],[6] Migraine can be unilateral or bilateral and can be further classified on the presence of an aura.[5] The occurrence of an aura has diagnostic relevance based upon the number of episodes and can encompass a range of sensory disturbance, not solely limited to visual field effects.[5]

Pathophysiology

Vascular constriction was a prior central focus of migraine pathology, resulting in hypoperfusion and being resolved through compensatory vasodilation.[6],[15] Such alterations in blood flow have been observed in neuroimaging of migraine patients.[6],[16–18] There are further alterations in neuronal depolarization, termed cortical spreading depression.[6],[19],[20] There has been further demonstration of causality between cortical spreading depression and the activation of trigeminovascular circuitry.[6],[21] Implications of cortical spreading depression include changes in pH, nitric oxide concentration, and the glutamatergic system.[21] The trigeminovascular system consists of afferent fibers with a foundation in trigeminal ganglia, projecting peripherally to intracranial blood vessels and venous sinuses and to extracranial tissues.[6],[22] Trigeminal branches innervate the scalp, orbit, meninges, and mandibular regions.[8] Activation of the trigeminovascular system facilitates the release of vasodilatory-promoting neuropeptides (substance P, neurokinin A, calcitonin gene-related peptide, nitric oxide), and subsequent release results in vessel dilation and inflammation.[6],[13],[23],[24] Further effects include the activation of both the superior salivary nucleus and parasympathetic efferent fibers.[20]

Evidence from positron emission tomography scanning (a technique to measure regional cerebral blood flow as an index of neuronal activity) suggests that episodic dysfunction of the brainstem, with corresponding effects on the trigeminal system, is involved.[25] Weiller et al[25] confirmed brainstem activation (periaqueductal gray, dorsal raphe nucleus, and locus coeruleus) at the onset of migraine headaches in a small sample of patients, and this area may represent an endogenous “migraine generator.” Whereas the brainstem may be regarded as an anatomic point of initiation, sensory information in migraine is propagated via higher regions of the hypothalamus, thalamus, and cortex. Sporadic dysfunction of the nociceptive system (periaqueductal gray and dorsal raphe nucleus) and the neural control of cerebral blood flow (dorsal raphe nucleus and locus coeruleus) are hypothesized to trigger migraine headache via effects of these brain structures on the trigeminovascular system.

The therapeutic effects of drugs that stimulate 5-HT$_1$ receptors (e.g., dihydroergotamine, sumatriptan), antagonize 5-HT$_2$ receptors (e.g., cyproheptadine), prevent 5-HT reuptake (e.g., amitriptyline) or release (e.g., calcium-channel blockers), or inhibit brainstem serotonergic raphe neurons (e.g., valproate) all lend support to the hypothesis that 5-HT is an important mediator of migraine. Furthermore, brainstem nuclei activated during migraine have high densities of serotonergic neurons. Specific 5-HT receptor subtypes, 5-HT$_{1B}$ and 5-HT$_{1D}$, are largely distributed in blood[26] and nerves,[27] respectively. These same 5-HT receptor subtypes are the targets of antimigraine drugs such as the triptans and ergot alkaloids.

GENETICS

The genetic basis of migraine is perhaps most effectively understood within the context of familial hemiplegic migraine. This subtype has been further categorized into multiple mutation-induced forms with associated genes CACNA1A, ATP1A2, SLC1A3, SLC4A4, and SCN1A.[6],[28] Such genes encode α_1 subunits (CACNA1A, SCN1A) and α_2 subunits (ATP1A2), or are linked with glutamate-associated (SLC1A3) and sodium-bicarbonate-associated (SLC4A4) transporters.[6],[28] The former α-subunit encoders regulate ion passage through calcium and sodium channels. A further genetic linkage with migraine pathology has been identified in the potassium channel, TRESK.[28] Implications of mutations at this level impact neuronal resting membrane potential, because an identified frameshift mutation negates TRESK action.[28],[29] There is further support for the influence of genetics on migraine pathology when considering the disproportionate prevalence across gender. Because prevalence is higher for females, polymorphisms of the estrogen receptor-1 (ESR-1) gene have been associated with increases in migraine risk.[1],[30],[31] Advances in the understanding of the genetic bases for pathology maintain importance, as such developments impart promise for novel interventional strategies.

Migraine pathology is multifaceted and neuroanatomically diffuse, involving the brainstem trigeminal nuclei, trigeminovascular afferents, thalamus, hypothalamus, CTZ, and cortical regions. Therapeutic strategies target the dysfunction in these regions, the mediation of associated symptomatology, and the modulation of neuropeptides and neurotransmission.

Quantitative Assessment Instruments

Various patient assessment instruments used to evaluate headache impact include the Headache Impact Test (HIT-6), Migraine Disability Assessment (MIDAS), and the Migraine-Specific Quality of Life Questionnaire (MSQ). The HIT-6 utilizes a Likert scale and evaluates pain, social and cognitive function, and psychological impact.[32],[33] A higher score on this assessment confers a greater headache impact. Rendas-Baum et al.[33] confirmed validation of this instrument in the context of chronic migraine. The Migraine Disability Assessment (MIDAS) is a self-administered, 7-item questionnaire, assessing headache-induced absenteeism, activity limitations, and headache frequency and intensity. This instrument has demonstrated reliability[34] and validity.[34–36] A regression analysis confirmed a significant, independent association between MIDAS score and pain intensity, headache frequency, and patient age.[34] The MSQ addresses migraine impact across patient social activity, emotional activity, and the capacity of migraine to prevent activity.[33] With established validity and reliability,[37–39] strong correlations between the MSQ and HIT-6 have been confirmed in the context of chronic migraine.[39]

MIGRAINE WITHOUT AURA

CASE 58-1

QUESTION 1: L.P. is a 27-year-old female presenting to her primary care physician (PCP) with a chief complaint of a "severe, throbbing headache." L.P. reports that headaches began 18 months ago, but during the past 3 months, headaches have been occurring with greater frequency, approximating one episode every 2 to 3 weeks. She further describes bilateral headache pain, occurring "without warning," and coinciding symptoms of nausea and vomiting, photophobia, and suboccipital pain. Prior episodes have been self-treated with acetaminophen 500 mg (4–8 tablets/episode as needed) with variable efficacy. Her past medical history is significant for generalized anxiety disorder, gastroesophageal reflux, and seasonal allergies. Current medication usage includes levonorgestrel/ethinyl estradiol 0.10/0.02 mg by mouth daily, venlafaxine XR 75 mg by mouth daily for generalized anxiety disorder (GAD), and omeprazole 20 mg by mouth daily × 2 months for recent-onset gastroesophageal reflux disease symptoms. Social history is negative for both tobacco use and illicit substances. L.P. reports the "occasional" consumption of alcohol, stated as "1 to 2 cocktails after work on Fridays." As headaches have occurred with greater frequency, absenteeism from work has resulted and this issue has prompted a visit with the PCP. Physical and neurologic examinations are unremarkable.

What subjective and objective information is consistent with a migraine diagnosis, and how do these signs/symptoms differ from tension-type headache?

Symptoms reported by L.P. are consistent with migraine. A study by Kelman addressed migraine location, reporting unilateral character in 67% of study subjects and bilateral character in nearly 24%.[40] For L.P., migraine location would not be a differentiating characteristic between migraine and tension headache, because tension headache is more commonly associated with bilateral character.[9] Pain quality, described as "severe" and "throbbing," is consistent with migraine and precipitates interruptions with daily activity (e.g., absenteeism from work) contrasted with tension headache which is associated with sensations of tightness.[9] Similarly, the occurrence of nausea, vomiting, and photophobia more appropriately aligns with migraine.[5]

Migraine prevalence is higher in female patients than in male patients, approximating 17%[2] with a cumulative incidence in females of 43%.[41] Migraine prevalence within the range of 18 to 29 years has been reported as nearly 21%.[2] L.P.'s sex and age would be compatible with prevalence data although it should be noted that a 28% prevalence statistic for females has been reported in the age range of 30 to 39.[2]

CASE 58-1, QUESTION 2: Which characteristics may be classified as precipitating factors, or "triggers," for migraine pathology? What are possible precipitating factors in L.P.?

Factors involved in precipitating migraine should be routinely assessed for all patients. Assessment should address factors within a patient's medical history, medication usage, social history, and environment. L.P.'s medical history is significant for GAD, she denies the usage of tobacco and illicit substances, she does report the occasional use of alcohol. Alterations in neurotrophic factors and an increase in anxiety symptoms have been demonstrated in migraine patients.[42] Such evidence imparts value to assess this aspect of L.P.'s medical history. While the consumption of alcohol should be addressed, the linkage between alcohol consumption and precipitating migraines is less clear.[43],[44] The potential provocation of cortical spreading depression, an electrophysiologic factor underlying migraine pathology, in association with alcohol has been suggested.[45] Although not reported by L.P., an evaluation of diet may provide useful information in determining migraine triggers. The evaluation of dietary patterns and quality has yielded disparities, reporting lower-quality dietary intake in migraine patients.[46]

CASE 58-1, QUESTION 3: Are further diagnostic and laboratory tests indicated in the case of L.P.?

The most important diagnostic evaluations of patients presenting with headache should be based on a thorough medical history and physical examination. Imaging (e.g., CT scans, MRI) is generally not required in the context of uncomplicated migraine.[47]

The report of symptoms by L.P. is consistent with migraine and is sufficient for diagnosis. Her symptoms are not associated with a secondary cause, such as trauma or other injury to the head or neck, and her neurologic examination is unremarkable. Similarly, without reason to suspect subarachnoid hemorrhage or symptoms secondary to meningitis, lumbar puncture would not be indicated. Clinical manifestations that may warrant neurologic imaging to identify artifacts or structural anomalies include coordination deficits, localized neurologic pathology, sensory manifestations, an abnormal neurologic examination, or the presence of atypical headache characteristics.[7],[47] Further, a change in headache character and headache onset with advanced age warrants neuroimaging.[7]

CASE 58-1, QUESTION 4: What are the goals of therapy for the management of headache in L.P.?

The approach to management and the treatment objectives for L.P. include resolving the acute symptoms of pain, nausea, and photosensitivity, educating L.P. on both prescription and self-care treatment, addressing the contribution of past medical history and concurrent medication usage to headache episodes, and identifying potential triggers.

CASE 58-1, QUESTION 5: What is the most appropriate recommendation with regard to the use of acetaminophen to treat headache episodes in L.P.?

L.P. has confirmed self-treatment of headaches with acetaminophen, and in such instances, it is critical to not only evaluate each patient's potential for self-care but also determine whether self-care treatment options can effectively and safely manage the diagnosis. Reported efficacy of acetaminophen has been mixed. Evidence does support acetaminophen efficacy in the migraine patient,[48],[49] and comparisons of acetaminophen with placebo yielded a nearly 20% difference in headache resolution.[48],[49] However, a study evaluating the parenteral administration of acetaminophen for acute management found no significant difference in efficacy versus placebo.[48],[50] Considering L.P.'s report of "variable efficacy" and increase in headache frequency, she is not an appropriate self-care candidate and continued, routine use of acetaminophen to manage acute episodes is not recommended.[48]

CASE 58-1, QUESTION 6: What drug-related problems associated with the precipitation or worsening of migraine should be addressed in L.P.?

Oral contraceptives may either worsen or precipitate migraine attacks in women without a previous history of this problem.[51] Incidence may be related to estrogen dose[52] and/or duration of oral contraceptive use.[52],[53] Alternatively, migraine has been implicated as an effect of estrogen withdrawal.[52],[54] Such patients may benefit from use of a continuous combined oral contraceptive product (e.g., one with no hormone-free interval), use of low-dose estrogen supplementation after 21 days of active contraceptives, or the use of a progestin-only oral contraceptive.[51],[55],[56]

The American Congress of Obstetricians and Gynecologists supports oral contraceptive use in migraine patients, but recommend avoidance in patients with tobacco use, in those 35 years or older, and/or in those with the presence of neurologic signs.[57] None of these factors are present in L.P.; therefore, oral contraceptive use may be continued. However, the implications of oral contraceptive usage and headache should be discussed with L.P. to allow for informed decision-making.

Further, consultation with L.P. should address whether GAD is being optimally managed. The innervation of trigeminovascular circuitry by neurotransmitters (e.g., norepinephrine, 5-HT) linked to affective pathology (e.g., anxiety, depression) has been established[58] and is known to coexist with such patients reporting increased headache frequency.[59] It is prudent to address anxiety management with L.P. and to further assess her response to venlafaxine to determine whether dose adjustments or medication changes are warranted.

CASE 58-1, QUESTION 7: Identify treatment strategies and recommend a medication as a first-line treatment option for the management of migraine in L.P.

Treatment should be aimed at rapidly resolving symptoms and the restoration of the patient's routine activity.[47],[60] Migraines may be managed via a "step" or "stratified" approach.[60],[61] With a "step" care model, conventional analgesics are initiated first with the opportunity to progress to using more targeted therapies as necessary.[60],[61] A "stratified" care model is based on the character of the migraine and will further incorporate validated assessment measures into the treatment decision.[60],[61] In this model, a more targeted, migraine-specific treatment may be considered first line. A comparison of treatment approaches has favored the "stratified" model.[61] The current treatment approach for L.P. has mimicked a "step" care model, using acetaminophen as a first-line medication.

Triptans (5-HT$_{1B/1D}$ Receptor Agonists)

Triptans, categorized as first (sumatriptan) and second generation (zolmitriptan, naratriptan, rizatriptan, almotriptan, frovatriptan, and eletriptan), are effective and well tolerated in acute migraine management and are considered appropriate for those not responsive to conventional analgesics.

Triptans can be compared on the basis of efficacy, onset, and recurrence potential. Naratriptan and frovatriptan demonstrate lower recurrence potential whereas the remaining agents within the class (sumatriptan, rizatriptan, almotriptan, eletriptan, and zolmitriptan) yield higher efficacy and faster onset.[60] Compared with ergot derivatives, triptans exhibit greater receptor subtype specificity, targeting 5-HT$_{1B}$ and 5-HT$_{1D}$ receptors.[60],[62] It is important to note that the specific nature of the effect differs according to receptor subtype. Constriction of the vasculature is mediated via 5-HT$_{1B}$ interaction[60],[62],[63] whereas interaction via 5-HT$_{1D}$ antagonizes release of neuropeptides.[60],[63] Triptans further diminish neuronal excitability within the trigeminovascular circuitry,[64] and there is evidence of impact on nitric oxide-based signal transduction.[63]

Table 58-1 depicts dosing and pharmacokinetic parameters for the triptans.

Sumatriptan

Sumatriptan is the prototype of the triptan class and is available in several formulations, including an oral tablet, nasal spray, and subcutaneous injection (pen devices and a needle-free solution). A recent analysis confirmed efficacy relative to placebo across sumatriptan doses and formulations; however, subcutaneous delivery yielded a more robust analgesic response.[65] Migraine intensity and the character of associated symptoms (e.g., severity of nausea and vomiting, early-onset nausea) impact formulation selection. For patients who are nauseated and prone to vomit during an acute attack, the subcutaneous and intranasal dosage forms are preferred. Both formulations have a rapid onset of effect. Reduction in headache intensity is reported within 10 minutes after subcutaneous injection and within 15 minutes after administration of the nasal spray.[41] Comparisons of orally administered sumatriptan (doses of 25, 50, and 100 mg) have yielded higher efficacy rates relative to placebo in achieving headache relief at 2 hours.[66] Higher sumatriptan doses of 50 and 100 mg were superior to placebo in achieving headache relief at 4 hours.[66]

Comparative efficacy studies with sumatriptan have yielded mixed results. Subcutaneous sumatriptan is more effective and faster acting than dihydroergotamine (DHE) nasal spray.[67] When compared with subcutaneous DHE, subcutaneous sumatriptan is more effective at 1 and 2 hours, but the two treatments are equally effective at 3 and 4 hours.[68] In this trial, headache recurrence rates at 24 hours favored subcutaneous DHE.[68] Intranasal administration of these agents supports efficacy of sumatriptan for both headache relief and the relief of associated symptoms (e.g., nausea) 60 minutes after dosing.[69] Similar efficacy has been reported for comparison with almotriptan[70] and zolmitriptan,[65] with diminished efficacy being reported versus eletriptan[71] and rizatriptan.[65]

Adverse Effects

Although sumatriptan is well tolerated, there is some variability in the adverse effect profile across different formulations. In general, both oral and intranasal sumatriptan formulations are associated with a low incidence of systemic adverse events. Oral administration of sumatriptan has been associated with adverse effects including dizziness, fatigue, nausea, and vomiting,[66],[72] whereas intranasal administration may cause abnormal taste and nasal discomfort.[73],[74] Parenteral administration is associated with bruising, redness, and discomfort at the injection site.[75] Due to the risk of vasoconstriction associated with triptan use, special attention is required for patients with cardiovascular disease or risk factors. Although the rate of adverse cardiovascular events has been low,[76] sumatriptan should not be used in patients with uncontrolled hypertension, peripheral or cerebral vascular disease, Wolff-Parkinson-White syndrome or arrhythmias associated with other cardiac accessory conduction pathway disorders, coronary artery disease, previous myocardial infarction, Prinzmetal angina, or coronary vasospasm. The provocation of coronary artery spasm secondary to sumatriptan administration has been demonstrated in those with variant angina, an effect likely mediated via the 1B receptor subtype.[77] A baseline electrocardiogram is recommended for patients with potential cardiac risk prior to triptan administration, and such an intervention may be considered for those patients without cardiovascular risk factors experiencing chest tightness following triptan administration.[78] Initial dosing should occur under medical supervision for patients that possess cardiac risk factors but are deemed appropriate treatment candidates.

Drug Interactions

Drug interaction potential associated with sumatriptan centers on the modulation of serotonergic activity, the risk of serotonin syndrome, and the potential for additive vasoconstrictive properties. Serotonin syndrome potential exists with the concomitant use of sumatriptan and ergot derivatives, selective serotonin reuptake inhibitors (SSRIs), lithium, and/or monoamine oxidase inhibitors (MAOIs).[79] A 2006 Food and Drug Administration advisory further underscored the need for caution and consideration of risk versus benefit with combination use of triptans used in combination with SSRIs and serotonin norepinephrine reuptake inhibitors (SNRIs).[80]

The medication profile for L.P. includes venlafaxine, an SNRI, for the management of GAD; however, this does not exclude the possibility of using triptans to manage her migraines. The clinician should evaluate the entire regimen to ensure optimal management of all indications, and if the addition of a triptan is deemed appropriate, L.P. should be educated on the potential for interaction and the clinical implications of the combination. Because L.P. has attempted treatment with conventional analgesics, she would be a candidate for initiating sumatriptan.

Table 58-1

Dosing and Comparative Pharmacokinetic Parameters of Triptans

Pharmacokinetic Parameters of Triptans in Healthy Volunteers and in Patients With Migraine[a], [214-227]

Drug	Dose and Route of Administration	↓ T_{max} (hours)	↓ C_{max} (mcg/L)	↓ Bioavailability (%)	↓ $t_{1/2}$ (hours)	↓ AUC (mcg/L/hour)	↓ Plasma Protein Binding (%)
Almotriptan	↓ 12.5–25 mg orally	1–3	–	≈70	3–4	—	≈35
Eletriptan	↓ 20–40 mg orally	2	–	≈50	≈4	—	≈85
Frovatriptan	↓ 2.5 mg orally	3	4.2/7[b]	29.6	25.7	94	≈15
	↓ 40 mg orally	5	24.7/53.4[b]	17.5	29.7	881	
Naratriptan	↓ 2.5 mg orally	2	12.6	74	5.5	98	≈28
Rizatriptan	↓ 5–10 mg orally	1–1.5, 3.2[c]	–	45	2–3	—	14
Sumatriptan	↓ 6 mg subcutaneously	0.17	72	96	2	90	14–21
	↓ 100 mg orally	1.5	54	14	2	158	—
	↓ 20 mg intranasal	1.5	13	15.8	1.8	48	—
	↓ 6.5 mg/4 hours transdermal	1.1	22	–	3.1	110	14–21
Zolmitriptan	↓ 2.5 mg orally	1.5, 3[c]	3.3/3.8[b]	39	2.3/2.6[b]	18/21[b]	≈25
	↓ 5 mg orally	1.5, 3[c]	10	46	3	42	
	↓ 5 mg intranasal	3	3.93[d]	102[e]	≈3	22.4[d]	

[a] AUC, area under the curve; C_{max}, maximal drug concentration; T_{max}, time to maximal drug concentration; $t_{1/2}$ = terminal half-life.

[b] Value for men and women, respectively.

[c] Orally disintegrating tablets.

[d] Values based on 2.5-mg dose.

[e] Compared with oral tablet.

CASE 58-1, QUESTION 8: During her annual physical examination, L.P. reports success in managing her migraines with sumatriptan but notes that two doses are often required for resolution of symptoms. She inquires as to whether another triptan would be more effective. How do second-generation triptans compare with sumatriptan? Is an alternative triptan appropriate for L.P.?

Second-Generation Triptans

Second-generation triptans include almotriptan, eletriptan, frovatriptan, rizatriptan, naratriptan, and zolmitriptan. All triptans have demonstrated superiority to placebo in terms of efficacy.[62],[81] These agents differ based on the pharmacokinetic profile and the capacity for headache recurrence.[60],[82] Among the class, zolmitriptan, rizatriptan, eletriptan, and almotriptan are associated with a faster onset and higher likelihood of recurrence compared with naratriptan and frovatriptan, both of which have a slower onset of action with a lower risk of recurrence.[60],[82] Naratriptan, in particular, is metabolized by multiple isozymes, without strong enzymatic inhibition or induction potential, creating less potential for CYP-induced interactions[83] whereas frovatriptan is subject to a dual metabolic path via CYP1A2 and renal excretion.[62] Relative to sumatriptan, oral bioavailability of second-generation agents is increased.[83]

Meta-analyses have offered insight into triptan comparisons. For headache response at 2 hours, eletriptan 80 mg and rizatriptan 10 mg elicited higher response rates with sumatriptan 100 mg as the reference whereas eletriptan 20 mg, frovatriptan 2.5 mg, and naratriptan 2.5 mg were inferior to sumatriptan.[83] In assessing sustained freedom from pain, greater efficacy has been observed with rizatriptan 10 mg, eletriptan 80 mg, and almotriptan 12.5 mg.[83] The opposite effect in this efficacy endpoint for almotriptan 12.5 mg has been observed in a parallel-group investigation with sumatriptan 50 mg as a reference.[84] Further comparisons of 74 randomized trials found that among the triptans, eletriptan was associated with the greatest potential of producing a pain-free state at 2 hours and at 24 hours.[85] Favorable efficacy was further observed for rizatriptan (2 hours) and zolmitriptan (24 hours).[85] Comparisons between rizatriptan and frovatriptan have yielded similar pain-free outcomes at 2 hours and have favored frovatriptan for pain-free status at 4 hours.[86] More recently, a therapeutic endpoint of the combination of freedom from pain with no incidence of adverse outcomes has been used in studies involving migraines.[87–90] Using this endpoint as a primary measure of comparison between zolmitriptan (2.5 mg) and almotriptan (12.5 mg) in a multicenter European trial, both treatments were deemed equally efficacious.[87]

Drug Interactions

Striking the balance between theoretic drug interaction risk for triptans and what is observed in clinical practice presents a challenge, especially because it relates to the risk of serotonin syndrome.[80],[91],[92] For L.P., potential drug interactions exist between triptans and venlafaxine (SNRI) and levonorgestrel/ethinyl estradiol (oral contraceptive). Attributed to metabolism via CYP1A2, a slight increase in frovatriptan AUC has been observed with oral contraceptive administration.[93] Prospective investigations assessing the combination of paroxetine and rizatriptan[91] and fluoxetine and zolmitriptan[91] found no instances of serotonin syndrome. These studies lie in contrast to reports of symptoms of serotonin syndrome with the combination of triptans and SSRIs or SNRIs.[41] The administration of a triptan should not be excluded based on L.P.'s medication profile; however, educating her on the potential for the interaction is warranted.

Increases in rizatriptan and zolmitriptan exposure have been observed secondary to MAO inhibition.[92] Inhibition of CYP3A4 has facilitated increases in eletriptan[92] and almotriptan.[92],[94]

L.P. can be considered an appropriate candidate for triptan prescribing. Although associated migraine symptoms are reported, the rapidity of onset for such symptoms (e.g., nausea, vomiting) is less clear and should be a point of discussion with the patient. Such information is important for the optimal formulation selection. A nonoral formulation may be recommended in the context of early-onset vomiting. Although a loss of efficacy is associated with triptan discontinuation,[95] the timeline for triptan use prior to discontinuation has spanned years.[95] Evidence for replacing one triptan with another is mixed. If treatment with one triptan results in suboptimal efficacy, an alternative triptan may be prescribed.[82] However, recent evidence evaluating the impact of such change does not suggest substantial benefit.[96],[97]

CASE 58-1, QUESTION 9: L.P. has noted that for some migraine episodes, nausea and vomiting has been severe, and asks about the use of DHE and antiemetics. What is the role of ergot alkaloids and/or antiemetics in migraine management?

ERGOT ALKALOIDS

Relative to triptans, ergot alkaloids function as receptor agonists with strong affinity at 5-HT_{1A}, 5-HT_{1B}, and 5-HT_{1D}.[98] In addition, these agents express activity at 5-HT_{1F}, as well as alpha and dopaminergic receptors.[98],[99] This pharmacologic profile differs from that of the triptans because the latter exhibit no affinity for dopaminergic or α-receptors.[98] Actions of ergot alkaloids are multifaceted, blocking neuropeptide release, stimulating the ventroposteromedial thalamus, and blocking transmission of afferent signals in trigeminal circuit.[98] Although ergot alkaloids have demonstrated benefit in managing migraine,[82],[100],[101] the more targeted pharmacologic profile of the triptans has gained preference.

Intranasal administration of dihydroergotamine has yielded significant improvements in both pain reduction and functional status in comparison with placebo.[102] A 2-mg DHE dose achieved headache resolution at 4 hours post administration for 70% of subjects, compared with 28% in the placebo group.[102] This level of efficacy at the 4-hour time point for DHE has been further substantiated in comparison with sumatriptan.[103] Subcutaneous administration of 1 mg DHE or 6 mg sumatriptan resulted in comparable headache resolution.[103] Functional capacity at 1 hour as well as the proportion of patients achieving pain relief at 2 hours postadministration favored sumatriptan.[103] Adverse outcomes of nausea, vomiting, and injection-site pain were more prominent for those administering DHE, whereas incidence of chest pain was more common in the sumatriptan-treated group.[103] Orally inhaled DHE represents a newer, noninvasive delivery (TEMPO inhaler, MAP Pharmaceuticals) system.[104],[105] Superiority to placebo has been demonstrated in the FREEDOM-301 Study across endpoints of pain relief and freedom from auditory sensitivity, light sensitivity, and nausea.[104] Associated adverse effects included product taste and nausea, 6% and 4%, respectively.[104] This delivery system is not yet commercially available.

Peripheral and cerebrovascular disease, renal and hepatic disease, sepsis, and cardiac disease qualify as contraindications to the use of ergot alkaloids.[98],[100] Further, with the potential to induce uterine contraction and distribute into breast milk, use is contraindicated during pregnancy and lactation.[98],[106] In patients with a history of hypertension, it is important to determine whether blood pressure is appropriately controlled before considering the use of these agents in migraine due to the potential for arterial constriction peripherally.[107] Compared with ergotamine, DHE exerts a more variable effect on blood pressure.[107]

Adverse Effects

Nausea is the most prominent adverse outcome with ergot alkaloids.[107] The effect is dose-related and is linked with 5-HT_2 and

---

5-HT_3 receptor activation.[60] Intranasal DHE and orally inhaled DHE have been associated with prolonged nasal congestion[60] and altered taste.[104] Parenteral administration has been associated with lightheadedness and leg cramping.[107]

Antiemetics

In most patients, triptan agents provide effective relief of migraine-associated nausea. Therefore, specific antiemetic therapy usually is not required. However, as mentioned previously, persistent nausea is more common in patients who use ergotamine for acute migraine therapy. In these patients, and in triptan-treated patients who experience incomplete nausea relief, adjunctive antiemetic therapy should be considered. Results from a more recent comparative trial (prochlorperazine IV 10 mg vs. metoclopramide IV 20 mg) found similar efficacy in managing nausea.[108] Efficacy of metoclopramide has been demonstrated at the lower end of the dosing scale (10 mg), but higher doses (20–40 mg) were not associated with improved outcomes.[109]

CASE 58-1, QUESTION 10: In addition to triptans and ergot derivatives, what other abortive agents are available for outpatient treatment of acute migraine?

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS AND COMBINATION ANALGESICS

Many NSAIDs and combination analgesics containing caffeine have been shown to be effective for the acute treatment of migraine headache.[110],[111] Significant clinical benefit in double-blind, placebo-controlled trials has been shown for aspirin, ibuprofen, naproxen sodium, and combination analgesics containing acetaminophen, aspirin, and caffeine.[47],[111],[112] Ketoprofen doses of 75 or 150 mg have demonstrated efficacy relative to placebo in reducing migraine severity.[113]

CASE 58-1, QUESTION 11: L.P. reports that her migraines have been successfully managed with naratriptan 2.5 to 5 mg/episode, with most episodes resolving with the lower dose. Naratriptan was selected on the basis of a lower likelihood of recurrence. L.P. has been experiencing a severe migraine for the past few days and has been unsuccessful in treating the episode with naratriptan. She has now sought treatment at a nearby hospital and has been diagnosed with status migrainosus. What is the most appropriate approach to managing status migrainosus in L.P.?

Intractable Migraine

Status migrainosus, or intractable migraine, is characterized by an extended duration of headache, exceeding 72 hours.[5] The typical management strategy usually requires hydration and parenteral therapy with ergot derivatives, sumatriptan, or opioid analgesics.

DIHYDROERGOTAMINE

Dihydroergotamine has demonstrated efficacy in treating intractable migraine by either intermittent or continuous administration.[114] The successful resolution of symptoms by DHE avoids the need for administration of corticosteroids and opioids for the same purpose. Adjunctive antiemetics should be administered for nausea.[114],[115]

SUMATRIPTAN

Sumatriptan 6 mg subcutaneously is also effective for the treatment of established migraine.[41] If the first injection does not provide relief at 1 hour, a second injection may be administered. Sumatriptan should not be administered within 24 hours of ergot alkaloids because of the potential for prolonged vasospastic reactions.

PROCHLORPERAZINE

Prochlorperazine has established efficacy in managing migraine-related nausea, with intravenous administration being effective during intractable migraine.[47],[114],[116] In randomized, controlled trials, prochlorperazine 10 mg IV was more effective than placebo, IV metoclopramide, IV ketorolac, and IV valproate for the treatment of acute migraine in the ED.[116]

CORTICOSTEROIDS

Parenteral dexamethasone may be administered in cases of intractable migraine.[114] Among a subset of patients experiencing migraine symptoms beyond 72 hours, a greater percentage of patients achieved pain-free status following parenteral dexamethasone administration, relative to placebo.[117] Further, lower headache recurrence has been observed in patients receiving dexamethasone after standard abortive treatment.[118]

L.P. may be treated with DHE, sumatriptan, prochlorperazine, or metoclopramide due to demonstrated efficacy and tolerability in comparison with other treatment options.[119]

CASE 58-1, QUESTION 12: During a return visit to her PCP, L.P. has reported that most migraine episodes have been successfully managed with naratriptan. Although effective, she expresses concern related to episode frequency noting that in some instances, she is using naratriptan 3 times weekly. Her PCP is considering prophylactic management and wants to prescribe propranolol. Is propranolol an appropriate option for L.P.?

Prophylactic Therapy

CRITERIA FOR USE

The relevance for initiating prophylactic therapy for migraine is not simply defined by one common feature among patients. Rather, the impact of migraine for an individual patient needs to be assessed. Estimates pertaining to prevalence suggest that only a small percentage (around 5%) receive prophylactic management.[120] Targeted outcomes for prophylactic therapy includes a reduction in both migraine frequency and severity, enhancing response to acute management strategies, and a general improvement in daily function.[120] As previous criteria have addressed the frequency of migraine episodes (two or more episodes monthly) as a principle consideration,[120] further guidance on suitability for such treatment should also address disability associated with the episodes, track record of failure with acute treatments or the overuse of acute treatments, adverse effects precipitated by acute treatments, or a more pathologically complex migraine (e.g., basilar or hemiplegic episodes, prolonged auras).[120],[121] Optimizing prophylactic treatment may likely require a 2- to 3-month window. This becomes an important consideration to convey to patients with a focus on maintaining adherence. Medications utilized in prophylactic migraine management generally fall into the categories of antihypertensives, antidepressants, or anticonvulsants. A fourth category comprised of nonprescription treatments is considered as well. The evaluation of evidence associated with prophylactic treatments is often challenging due to the lack of studies with comparisons between agents or with crossover design.

An evidence-based guideline for prophylactic treatment of migraine has been created by the US Headache Consortium, published through the American Academy of Neurology.[120] Further evidence has been provided via a combined panel of the American Academy of Neurology and the American Headache Society.[122] Migraine prophylaxis is an area for which the off-label use of medications is a particularly common practical consideration. Only a select number of agents have been approved by the Food and Drug Administration (FDA) for migraine prophylaxis in the US, including propranolol, timolol, topiramate, valproic acid or divalproex sodium, and botulinum toxin A (onabotulinumtoxinA). The approval of botulinum toxin is within the context of treating chronic migraine. Although triptans are not FDA-approved for migraine prophylaxis, select agents (frovatriptan, naratriptan, and zolmitriptan) are considered off-label for migraine prophylaxis during menstruation.

PROPRANOLOL

Evidence supports propranolol safety and efficacy in migraine prophylaxis.[120–123] Various mechanisms for efficacy may be considered, including the modulation of central catecholamines[124] and interaction with serotonin receptors.[124,125] Propranolol has also demonstrated a suppressive effect on cortical spreading depression in animal models.[124,126] In a small study of migraine patients, propranolol has decreased cerebrovascular reactivity, mediated by action on vascular tone.[127] For L.P., the prescribing of propranolol for migraine prophylaxis could be considered, as there are no contraindications within her profile that would prevent use. A limiting variable to continued use may be the adverse effect profile, including lethargy, fatigue, and sleep disruption.[122,128] As an alternative to propranolol, metoprolol could be considered similarly appropriate for L.P. Comparisons with aspirin[122,129] or propranolol[120] suggest that metoprolol would be appropriately effective. Metoprolol has been further compared with nebivolol.[130] While similarly effective in prophylactic migraine management, better tolerability and ease of titration were associated with nebivolol.[130]

Dosing

Initial dosing for propranolol for prophylaxis of migraine headaches is 20 mg by mouth 2 or 3 times a day with gradual titration (weekly intervals) according to patient tolerability to 80 to 160 mg/day in two to four divided doses.[121] Once the daily dosage of propranolol required to control headaches is established, patient adherence may be improved by changing to a long-acting oral dosage form (e.g., Inderal LA).

Migraine with Aura

CASE 58-2

QUESTION 1: V.M. is a 24-year-old female, reporting to her primary care provider with a 3-month history of "throbbing" headaches. Although V.M. has reported experiencing tension headaches "on and off" in the past, the character of these recent headaches has been different, accompanied by early-onset, severe, nausea and vomiting, and preceded by "flashes of light" and a unilateral facial "numbness." The "numbness" and visual flashes have typically resolved after 30 minutes with headaches developing soon after. She has taken naproxen or ibuprofen for treating recent episodes, but neither has proven effective. The MIDAS score was 11. Medical history includes hypothyroidism, treated with levothyroxine 100 mcg by mouth daily, and a past history of tension headache. Her medication profile also includes an oral contraceptive, norgestimate/ethinyl estradiol, for the past 5 years. She describes herself as an "occasional smoker" and denies a history of alcohol use or illicit substances. Which information is consistent with the diagnosis of migraine with aura in V.M.?

Although both the "throbbing" character of the headache and associated gastrointestinal (GI) symptoms are consistent with migraine, it is the presence of both the visual (light flashes) and sensory (numbness) disturbances correlate with the diagnosis of migraine with aura. Relevant information for confirming this diagnosis would be a minimum of two episodes, the accompaniment of an aura symptom, the duration and unilateral nature of the aura, and the evolution of the headache following the aura.[5]

Propagating glial and neuronal depolarization, characterized as cortical spreading depression, has been implicated in aura.[20],[131] It is suggested that the pathologic basis for aura involves gap junction modulation at the neuronal level of the trigeminovascular circuitry.[20] Aura has been associated with migraine in approximately one-third of patients[131] and visual phenomena are typically the most prevalent aura features.[131] It is important to note that visual effects are substantially varied and can include flashing lights, waving lines, or areas of localized blindness (scotoma).[132] Further, a "visual snow" effect has been described in the literature, bearing resemblance to television static.[133] Although visual phenomena are most prevalent, sensory disturbances (e.g., numbness, pins, and needles sensation) may also comprise an aura.[5] In the case of V.M., the aura includes both visual and sensory disturbance, and coupled with the report of additional symptoms (e.g., throbbing headache, n/v), a diagnosis of migraine with aura is appropriate. The temporal relationship between the aura and evolution of the migraine is one of further consideration. Although V.M. reports the evolution of the migraine following the aura, there is evidence to support classical migraine symptoms occurring during the aura phase.[134]

CASE 58-2, QUESTION 2: Should the migraine that V.M. is experiencing be treated according to a stratified-care or step-care model?

In accordance with a step-care model, a conventional analgesic medication would be considered as primary therapy.[61] A stratified-care approach is designed for treatment selection based on patient need.[61] V.M. has reported self-treatment with conventional agents (e.g., naproxen or ibuprofen) without adequate relief. Further considering that V.M.'s MIDAS score corresponds to "moderate" disability and the reported variance of MIDAS score with age,[34] a stratified-care model would be preferable.

CASE 58-2, QUESTION 3: V.M. has been counseled previously regarding the cardiovascular risks associated with oral contraceptives and questions whether she is at greater risk considering her migraine diagnosis. Is an oral contraceptive appropriate for V.M.?

No consistent increased risk for stroke has been found among men, women older than 45 years old, and women who have migraine without aura.[135] Among patients with a diagnosis of migraine with aura, a twofold increase in ischemic stroke risk has been reported.[136] An additional finding in this meta-analysis supported an increased risk among migraine patients using oral contraceptives.[136] The World Health Organization considers migraine with aura in women of any age an absolute contraindication to the use of combined oral contraceptives.[51] The American College of Obstetricians and Gynecologists guidelines permit the use of combined oral contraceptives in women who suffer from migraine with aura as long as they have no focal neurologic signs, do not smoke, and are younger than 35 years of age.[51] V.M. describes herself as an "occasional smoker" so relevant management strategies include discussing other contraceptive options and/or a smoking cessation plan.

CASE 58-2, QUESTION 4: What is the most appropriate recommendation for acute management of V.M.'s migraine?

Given the severity of symptoms and past treatment experience with conventional analgesics, the selection of a migraine-targeted treatment (e.g., ergot alkaloid, triptan) would be preferable. Of similar importance is the presence of severe, early-onset nausea; therefore, a nonoral administration is recommended. Sumatriptan and zolmitriptan are available as nonoral formulations, and either

---

could be considered appropriate for V.M. A limiting factor in the selection of ergot alkaloids as a primary treatment would be the potential for drug-associated nausea.[107]

CASE 58-2, QUESTION 5: V.M. has now returned to her PCP reporting success in managing her migraines with zolmitriptan. The frequency of migraine episodes remains an issue, reporting 4–5 episodes monthly which have caused her to miss work. Her PCP is considering prophylactic treatment but would prefer not to prescribe propranolol. Which medication may be prescribed to prevent migraines in V.M.?

AMITRIPTYLINE

Amitriptyline is an appropriate first-line therapy option for migraine prophylaxis[121],[137] with such effects being independent of antidepressant activity.[138–140] Demonstrated blockade of sodium currents in trigeminal neurons and blockade of 5-HT reuptake[141] is the basis for the potential efficacy in managing migraine,[140] although a complete mechanism has not been fully elucidated. Amitriptyline treatment has been associated with significant improvement in MIDAS scores[142] Such an effect has been demonstrated following a 45-day treatment cycle.[142] Particularly applicable to the case of V.M., there is demonstrated benefit for amitriptyline in the treatment of tension-type headache as well,[9] making it a viable option for patients with both headache forms.

Amitriptyline has been compared with propranolol, divalproate, and topiramate in various studies. A randomized trial comparing extended-release divalproate with amitriptyline (150 subjects in each treatment group) yielded similar efficacy, measured by headache frequency at 6 months, while being inferior to divalproate at 3 months.[143] Two separate studies have provided comparison between amitriptyline and topiramate.[144],[145] With a primary efficacy measure of monthly migraine episode rate, 100-mg doses of each proved comparable and similarly well tolerated.[144] A smaller study reported similar results; however, the combination treatment of amitriptyline and topiramate was assessed as a separate, third treatment arm.[145] Patient satisfaction among subjects taking the combination was noted to be higher relative to either monotherapy group.[145]

Dosing

The initial dose of amitriptyline is 10 to 25 mg by mouth at bedtime. This nightly dose can be increased at weekly intervals by 10 to 25 mg until the maximal dose of 150 mg/day is reached.

While generally tolerated, common adverse effects attributed to amitriptyline treatment have included drowsiness, anticholinergic effects, and weight increase.[143–145]

TOPIRAMATE

Topiramate is considered a first-line option for migraine prophylaxis.[121],[137] In addition to aforementioned comparisons with amitriptyline, prospective studies have reported similar efficacy between topiramate and sodium valproate.[146–148] Three large randomized, placebo-controlled trials have documented the efficacy of this agent for reducing the number of monthly attacks.[149] With initial dosing of 25 mg daily,[144],[145],[150] target doses of 100 mg daily[144] and 200 mg daily[150] have been assessed. Evidence supports dose titration to 100 mg for optimal outcomes.[148],[151] Further titration to 200 mg has not demonstrated significantly better outcomes relative to 100 mg.[148],[152]

Paresthesia, fatigue, weight loss, memory, and concentration deficits have been associated with topiramate therapy.[144],[145],[153]

VALPROATE

Valproate and divalproex sodium are approved for migraine prophylaxis and are viable treatment options for prevention.[121],[137] An extended-release divalproex sodium formulation has demonstrated efficacy relative to placebo.[154] Versus active comparators, equivalence in efficacy has been reported for propranolol[155] and topiramate.[147] The selection of valproate as a therapy for women of childbearing age must be evaluated cautiously, in light of potential detrimental effects in cognitive development.[156]

Dosing

Delayed- or extended-release formulations of divalproex sodium (e.g., Depakote or Depakote ER) may be prescribed for prophylaxis with the advantage of the latter formulation being once-daily administration. Initial dosing for the delayed-release formulation is 250 mg by mouth twice daily whereas the extended-release formulation is 500 mg by mouth once daily.

Adverse effects associated with valproate treatment include alopecia, nausea, drowsiness, and weight gain.[147] Potential for hepatotoxicity and pancreatitis[157] limits utility.

GABAPENTIN

Gabapentin possesses a complex mechanism of modulating Ca^{++} channels, increasing GABA concentration centrally, and binding to gabapentin-binding protein.[158] A randomized trial versus placebo demonstrated superiority of gabapentin 2,400 mg/day in reducing migraine rate over 4 weeks.[158] Secondary outcomes related to severity, functional capacity, duration, and aura severity did not yield significant differences between treatment groups.[158]

CANDESARTAN

Candesartan, an angiotensin II type 1 (AT_1) receptor antagonist, has demonstrated efficacy, based on an intention-to-treat analysis of 57 patients, in migraine prophylaxis in a randomized, placebo-controlled, crossover design.[159] Outcomes of migraine frequency (number of days) and duration (number of hours) were favorable with candesartan.[159] Although dizziness was the most frequently reported adverse event associated with treatment, neither this effect nor any other adverse outcome differed significantly from placebo.[159]

TONABERSAT

As both cortical spreading depression and gap junctional modulation have been linked with migraine aura,[20,131] the inhibition of CSD constitutes a potential approach to treatment.[160,161] Tonabersat functions as a gap junction blocker.[161] Comparisons with placebo have been mixed[160,162,163] with efficacy exclusive to migraine with aura.[160] Tonabersat is currently an investigational treatment.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Effectiveness as preventive therapy is considered to be modest compared with the first-line agents.[121] NSAIDs may be effective as short-term therapy for menstruation-associated migraine.[121]

In selecting an alternative prophylactic medication for V.M., evidence supports use of either a selective β-antagonist (e.g., metoprolol), amitriptyline, or topiramate. In all such instances, V.M. should be counseled with regard to dose titrations, adverse effects, and allowing for a sufficient trial duration to adequately determine efficacy.

Medication Overuse

CASE 58-3

QUESTION 1: L.D. is a 39-year-old woman with a 7-year history of migraine (without aura) and tension-type headache who comes to the clinic requesting a refill of her almotriptan. She reports an increase in the frequency of both her “throbbing” and “dull, pressure sensation” headaches during the past year, and lately she has had difficulty distinguishing the two types. In the past 2 months, she has had only 5 days with no headache, and she has been much less productive in her work as a magazine editor. She has reported using 4 to 5 almotriptan tablets weekly with multiple episodes also requiring naproxen sodium, which she has purchased over the counter (OTC). She has requested two refills for her almotriptan during the past 1½ months. What is the role of medication overuse in worsening symptoms, and how should this condition be managed in L.D.?

Medication overuse is defined as the use of triptans, ergot alkaloids, opioid analgesics, or combination analgesics on 10 or more days/month (the criterion for use of simple OTC analgesics is 15 or more days/month)[137] and often occurs in migraine and tension-type headache sufferers.[164] The pathophysiology of medication overuse headache is multidimensional and is related to hypometabolism in neuroanatomic structures,[164],[165] neurochemical alterations (e.g., orexinA, corticotropin-releasing factor),[166] and alterations in receptor expression and neuropeptide levels (e.g., increase in CGRP).[167] Chronic daily headaches often have features of both migraine and tension-type headaches.[168] L.D. displays many of the features of medication overuse headache. She reports an increase in the frequency of headaches to a near-daily pattern, and she is no longer able to distinguish between migrainous and tension-type headaches. Laboratory tests should be ordered to assess L.D.'s renal and hepatic function, and she should be questioned regarding the occurrence of GI discomfort, acute bleeding, or a change in her stool color.

In general, patients who receive abortive agents for headache treatment should be counseled to restrict their use of these agents to no more than twice/week.[121] The design of medication withdrawal procedures can be tapered or abrupt, with a tapered withdrawal procedure recommended for opioid, barbiturate, or benzodiazepine overuse.[168] Abrupt discontinuation can be considered suitable for triptans and nonopioid analgesics.[168] For L.D., the discussion of a discontinuation strategy would be recommended. Such an intervention has demonstrated positive outcomes in headache reduction.[169],[170] Further, prophylaxis may be considered and topiramate has demonstrated efficacy in this context.[168],[171]

CLUSTER HEADACHE

Cluster headache is an uncommon headache disorder (estimated prevalence 0.07%–0.4%) that derives its name from the characteristic pattern of headache recurrence—headaches tend to occur nightly during a relatively short time (e.g., several weeks or months), followed by a long period of complete remission.[172] Cluster headache is more common among males with an average age of onset around 30 years.[173]

Cluster headache is characterized by severe, unilateral pain, potentially described as a pulsating or burning sensation, often involving the orbital, temporal, or maxilla regions.[5],[174] In addition to pain, cluster headache typically involves autonomic features (e.g., miosis, nasal congestion, ptosis, lacrimation).[5],[174]

Pathophysiology

The pathology surrounding cluster headache includes stimulation of parasympathetic outflow, disturbance at the level of the hypothalamus, and vasodilation.[175],[176] Such pathology is also a function of alterations in testosterone levels,[175] melatonin,[175] and diminished response to thyrotropin-releasing hormone.[175] Further assessments of pineal functioning in the context of cluster headache have revealed anomalies in serial plasma melatonin sampling, reflected as diminished peaks.[177] The pathology further includes angiographic changes and the interplay of parasympathetic and sympathetic function at the level of the cavernous sinus.[178]

Signs and Symptoms

CASE 58-4

QUESTION 1: R.H. is a 31-year-old man with a 3-year history of episodic cluster headache. He has been headache-free for the past year, but today states that the headaches are returning in their characteristic fashion. He reports abrupt onset of right-sided retro-orbital pain with occasional superimposed knifelike "jabs" that increase in intensity for several minutes to a severe, unrelenting pain lasting about 90 minutes. The headache then gradually subsides. Associated symptoms include right-sided lacrimation, conjunctival injection, and rhinorrhea. He denies any premonition of ensuing headache or GI upset during the attacks. Physical examination during a cluster headache shows right eyelid droop and pupillary miosis. R.H.'s cluster periods characteristically last about 2 months and usually recur once or twice yearly. The first headache of the current episode awoke him from a short nap. R.H. expects to suffer one or two such headaches daily because this has been the usual pattern during each cluster period. Previous cluster headaches have been symptomatically treated with aspirin and codeine 30 mg. However, R.H. reports only modest relief with this treatment approach.

R.H.'s medical history is unremarkable. He does not use tobacco but admits to occasional social drinking. What subjective and objective evidence in this case is consistent with a diagnosis of cluster headaches?

R.H.'s sex, age of onset, quality and intensity of headache pain, periodicity of headache attacks, and associated symptoms all support the diagnosis of cluster headaches.

An aura may precede a cluster headache episode; however, this effect occurs in a small percentage of patients.[174],[179] The episodic timeline of cluster headache is variable, extending from weeks to months, with the potential for extended remission periods.[5] R.H.'s headache quality (severe, unrelenting pain), site (unilateral), evolution and resolution pattern (worsens over several minutes and resolves within 90 minutes), and periodicity of attacks (one or two headaches occurring daily for about 2 months followed by a period of remission that lasts about 1 year) are all compatible with the usual character of cluster headaches.

Associated symptoms reported by R.H. during headache attacks (e.g., lacrimation, rhinorrhea, conjunctival injection) and the absence of GI or neurologic disturbances are also compatible with the diagnosis of cluster headaches.

CASE 58-4, QUESTION 2: What abortive measures are available for symptomatic treatment of individual headaches during R.H.'s current cluster period?

Abortive Therapy

The treatments of choice for abortive treatment of cluster headaches are sumatriptan by subcutaneous injection, zolmitriptan nasal spray, and oxygen inhalation.[180],[181] Among these agents, subcutaneous sumatriptan is often preferred.[182]

SUMATRIPTAN

Sumatriptan 6 mg administered subcutaneously for cluster headaches reduced severity in 74% of attacks within 15 minutes,

---

compared with 26% of attacks treated with placebo.[182] An additional injection of 6 mg does not appear to give additional headache relief.[182] However, in patients who experience a recurrent headache after initial relief with sumatriptan, a second injection is often useful.[176] Sumatriptan should not be used more often than twice daily during cluster bouts.

A randomized, multicenter trial, assessing intranasal sumatriptan (20 mg) compared with placebo, yielded a significantly better outcome of decreased pain response, 30 minutes following administration.[183] Secondary outcome measures, including resolution of associated symptoms, similarly favored sumatriptan.[183]

OXYGEN

Oxygen may be useful for patients with frequent cluster headaches who would otherwise exceed maximal dosing restrictions of sumatriptan.[172] The mechanism of oxygen's effect is unknown but may be related to a direct vasoconstrictive action.[172] Clinical trial data have been mixed. In a trial of 57 patients with episodic cluster headache, 100% oxygen delivered at 12 L/minute was deemed more effective versus placebo for achieving pain-free status at 15 minutes.[184] A double-blind, placebo-controlled cross-over study of hyperbaric oxygen treatment for cluster episodes imparted no significant beneficial effect relative to placebo.[185]

ZOLMITRIPTAN

Two controlled trials have established the effectiveness of intranasal zolmitriptan for the acute treatment of cluster headache attacks. Cluster headache relief rates were 40% and 50% with 5 mg of zolmitriptan, and 62% and 63% with 10 mg of intranasal zolmitriptan in these two studies, respectively.[181],[186]

OTHER THERAPEUTIC INTERVENTIONS

The somatostatin analog, octreotide, administered by subcutaneous injection, has demonstrated superiority in efficacy relative to placebo.[187] In addition to headache relief at 30 minutes, octreotide administration yielded improved outcomes for resolving associated cluster headache symptoms.[187] Alternate therapeutic interventions include intranasal capsaicin,[188] local administration of cocaine, and the local administration of lidocaine.[189]

Reasonable options for the acute treatment of R.H.'s acute cluster headaches include subcutaneous sumatriptan, oxygen inhalation, and intranasal zolmitriptan. For many patients, oxygen is a less convenient therapy because the equipment is not easily portable and the patient must sit still during the treatment. The choice can be made on the basis of patient preference or cost.

CASE 58-4, QUESTION 3: What therapeutic agents are available for headache prophylaxis during an active cluster period? Which option is most appropriate for R.H.?

Prophylactic Therapy

Prophylaxis should be considered in the context of chronic cluster headache episodes. An important objective for prophylactic treatment is reducing the risk of overmedication associated with acute treatment.[175]

VERAPAMIL

Evidence supports verapamil efficacy in cluster headache prophylaxis[174],[175],[190–192] with daily doses in the range of 240 to 320 mg.[175],[193],[194] Baseline and periodic electrocardiography should be performed for those maintained on verapamil therapy.[174],[175] The need for such monitoring is a function of verapamil's electrophysiologic effects on cardiac nodal tissue.

LITHIUM CARBONATE

Where primary treatment is either ineffective or contraindicated, the use of lithium as a second-line option is supported.[191] A double-blind, crossover study found similar efficacy relative to verapamil yet, lithium was inferior to verapamil in tolerability.[195] Lithium serum levels associated with efficacy in cluster headache prophylaxis are usually between 0.4 and 0.8 mEq/L.[182] In addition to assessing serum levels, routine monitoring of electrolytes, hepatic, renal, and thyroid function is required.[191]

SUBOCCIPITAL STEROID INJECTION

One high-quality randomized, controlled trial demonstrated the efficacy of suboccipital steroid injection for the prophylaxis of cluster headache in 26 patients.[196] Injections included 12.46 mg of betamethasone dipropionate and 5.26 mg of betamethasone disodium phosphate mixed with 0.5 mL of 2% lidocaine. Eighty-five percent of patients had relief of headache attacks within 72 hours of injection (compared with none in the placebo group).

TOPIRAMATE

Topiramate has demonstrated efficacy for cluster headache prophylaxis.[191],[197–201] In a study of patients with prior prophylactic treatment exposure, topiramate produced favorable outcomes, inducing remission in greater than 50% of treated patients.[197]

Prompt consideration should be given to the aforementioned additional treatments if suppression of headaches during the cluster period is warranted. In general, after response to prophylactic agents such as verapamil and lithium has been established and maintained for at least 2 weeks, attempts can be made to discontinue the drug. Treatment should be reinstituted if headaches recur. With considerations toward patient ease of use and efficacy, treating R.H. with verapamil or topiramate would be rational.

TENSION-TYPE HEADACHE

Prevalence of tension-type headache is variable but has been shown to be as high as 78%.[5],[202],[203] Women are slightly more affected by tension-type headaches than men, with a ratio of 5:4.[204] Tension-type headache is typically bilateral and is characterized by a milder pain intensity and a tightening quality.[5] Nausea and vomiting are not typical of tension headache presentation but photo- or phonophobia may be present.[5]

Headache frequency is an important determinant for tension headache classification, expressed in terms of headache days/month.[5],[202] Episodic tension headache can be either infrequent (<1 day/month) or frequent (1–14 days/month), whereas chronic tension headache is classified with a threshold of 15 headache days/month.[5],[202]

Pathophysiology

The pathology of tension headache is theorized to be a function of both peripheral and central pain pathways.[205] Modulation of trigeminal nociceptors and pericranial muscle strain fit within this pathology.[205]

General Management and Abortive Therapy

CASE 58-5

QUESTION 1: K.B., a 27-year-old female financial analyst, presents to her general practitioner with a complaint of recurring headaches

---

that worsened when she started her current job. Before this time, she had experienced infrequent headaches, which she associated with periods of stress. The headaches would occur 3 to 4 times yearly, were of a constant, dull, or "pressing" character, and were present around the entire head. Recently, headaches of similar character have been occurring about 1 to 2 times weekly, usually toward the end of her workday. The pain usually lasts the rest of the day but varies in intensity. Occasionally, a headache is present when she wakes up in the morning as well. K.B. denies GI and aura symptoms associated with her headaches. She has noticed that relaxation and alcohol ingestion seem to relieve these headaches, but aspirin and acetaminophen have been ineffective. Her blood pressure is 120/74 mm Hg; her physical and neurologic examinations are completely normal. What measures should be taken to relieve K.B.'s headaches? What is an appropriate goal for treatment?

K.B. appears to be suffering from frequent episodic tension-type headaches. She reports approximately four to eight headache episodes/month, and these headaches have features that are stereotypical for tension-type headache. As in the treatment of other chronic headache disorders, a cure for recurrent tension-type headache is unlikely. K.B. should clearly understand that the goal of treatment is a reduction in the frequency and severity of headache. Drug therapy and relaxation techniques are the primary means by which tension-type headaches are treated.

ANALGESICS

Conventional analgesics, including NSAIDs, are appropriate first-line treatments for tension headache.[202] A recent meta-analysis of four controlled trials supported the effectiveness of both a combination product (acetaminophen, aspirin, and caffeine) and acetaminophen relative to placebo in achieving pain-free status at 2 hours postadministration for tension headache treatment.[206] Secondary endpoints included pain-free status at 1 hour post, headache response at 2 hours, and level of impact on daily activity, with results being consistent with the primary outcome measure.[206]

An NSAID (e.g., ibuprofen or naproxen) would be an appropriate recommendation for the treatment of K.B.'s tension-type headaches because of her previous inadequate responses to aspirin and acetaminophen.

CASE 58-5, QUESTION 2: K.B. was prescribed ibuprofen 400 mg every 4 to 6 hours as needed for acute relief of recurrent tension-type headaches. At her next scheduled follow-up visit, K.B. reported moderate relief with ibuprofen but complained of GI upset with each dose, even when taken with food. What prophylactic agents are available for continuous suppression of K.B.'s tension-type headaches?

Prophylactic Therapy

Prophylaxis is relevant in the context of both frequent, episodic tension headache and chronic tension headache.[202] Amitriptyline has demonstrated efficacy in managing tension headache.[202],[207] A median daily dose of 75 mg yielded a significant improvement in headache index relative to placebo.[207] Mirtazapine and venlafaxine have both demonstrated efficacy in tension headache treatment relative to placebo.[208],[209] Superiority for mirtazapine was demonstrated in measures of headache frequency, intensity, and duration for patients with prior treatment experience.[208]

Given K.B.'s increasing frequency of tension-type headache and her intolerance to moderate doses of ibuprofen, prophylactic treatment with amitriptyline would be appropriate. A starting dose of amitriptyline 10 mg nightly, increasing by 10 to 25 mg at 1-week intervals to a maintenance dose of 50 mg/day, should be prescribed, at which time headache response can be assessed and the dose increased or decreased as necessary. If effective, amitriptyline should be continued for 3 to 4 months before gradually decreasing the dose until the drug is completely discontinued. Therapy should be reinstituted if headaches return. Mirtazapine may be initiated as a second-line option for K. B., if amitriptyline is not effective.

Interprofessional Management

Practices in the areas of spiritual meditation,[210] cognitive therapy and stress reduction,[211],[212] and acupuncture[213] have been assessed in headache management. A recent study, assessing outcome measures of headache frequency, severity, and medication use, as impacted by either spiritual meditation, secular meditation (internally and externally focused), or muscle relaxation, reported a favorable impact on episode frequency induced by spiritual meditation.[210] A decrease in medication usage was similarly reflected in this cohort; however, neither pain sensitivity or severity differed.[210] Interventions directed toward stress reduction, while deemed feasible, have not met statistical significance for changes in headache severity or frequency.[211] Although stress reduction favorably impacted MIDAS and HIT-6 assessments relative to controls, the study lacked the statistical power to confer significance.[211] Similarly, traditional acupuncture has yielded headache-associated pain relief; however, prospective trials are warranted to better elucidate the therapeutic impact of this practice.[213]

Parkinson's Disease and Other Movement Disorders

Kristin M. Zimmerman and Natalie Whitmire

CORE PRINCIPLES		CHAPTER CASES
1	Parkinson's disease (PD) is a chronic, progressive movement disorder resulting from loss of dopamine from the nigrostriatal tracts in the brain, and is characterized by rigidity, bradykinesia, postural disturbances, and tremor.	**Case 59-1 (Questions 1, 2)**
2	Treatment for PD is aimed at restoring dopamine supply through one, or a combination, of the following methods: exogenous dopamine in the form of a precursor, levodopa; direct stimulation of dopamine receptors via dopamine agonists; and inhibition of metabolic pathways responsible for degradation of levodopa.	**Case 59-1 (Questions 3–17)**
3	Therapy for PD is usually delayed until there is a significant effect on quality of life; generally younger patients start with dopamine agonists or monoamine oxidase type B (MAO-B) inhibitors, whereas older patients may start with levodopa.	**Case 59-1 (Questions 3,4), Figure 59-2**
4	Initial therapy with levodopa-sparing agents is associated with a lower risk of developing motor complications than with levodopa, but all patients will eventually require levodopa.	**Case 59-1 (Questions 4–9), Figure 59-2**
5	Advanced PD is characterized by motor fluctuations including a gradual decline in on-time, and by the development of troubling dopaminergic-induced dyskinesias. Modified carbidopa/levodopa formulations, dopamine agonists, MAO-B inhibitors, and catechol-O-methyltransferase (COMT) inhibitors can reduce motor fluctuations; amantadine can improve dyskinesias. Deep brain stimulation of the globus pallidus interna or subthalamic nucleus may benefit patients with advanced PD.	**Case 59-1 (Questions 13–19), Figure 59-4**
6	Antioxidants, dietary supplements, and other investigational therapies have been studied for the management of Parkinson's disease.	**Case 59-2 (Question 1)**
7	Comprehensive therapy for patients should include attention to many progressive complications of PD, including neuropsychiatric disturbances and autonomic dysfunction.	**Case 59-3 (Questions 1, 2)**

RESTLESS LEGS SYNDROME

1	RLS is a disabling sensorimotor disorder typically marked by irresistible urge to move the legs (akathisia). It is often associated with	**Case 59-4 (Question 1)**

	uncomfortable paresthesias or dysesthesias and often occurs in the evening or night.	
2	Several conditions are associated with or can aggravate RLS. Periodic limb movements of sleep (PLMS) is not the same as RLS but often coexists.	**Case 59-4 (Question 2)**
3	Dopamine agonists are first-line treatments for RLS. They are preferred because they are longer acting than levodopa, and reduce symptoms throughout the entire night. Other effective therapies include carbidopa/levodopa, gabapentin, benzodiazepines, and opiates.	**Case 59-4 (Question 3)**
4	A common problem with long-term use of dopaminergic agents in RLS, particularly levodopa, is an augmentation effect. This refers to a gradual dosage intensification that occurs in response to a progressive worsening of symptoms after an initial period of improvement. Gradual withdrawal of therapy and substitution with other agents should be performed, rather than continued dopaminergic dose escalation.	**Case 59-4 (Question 4)**

ESSENTIAL TREMOR

1	Essential tremor should be distinguished clinically from tremor associated with PD or other causes.	**Case 59-5 (Question 1)**
2	Treatments of choice for essential tremor include propranolol or primidone. In refractory cases, targeted botulinum toxin A injections can be useful.	**Case 59-5 (Question 2)**

PARKINSON’S DISEASE

Incidence, Prevalence, and Epidemiology

PD is a chronic, progressive movement disorder first described in 1817 by Dr. James Parkinson. Since that time, the term parkinsonism has come to refer to any disorder associated with two or more features of tremor, rigidity, bradykinesia, or postural instability.[1] Most cases of PD are of unknown cause and referred to as idiopathic parkinsonism; however, viral encephalitis, cerebrovascular disease, and hydrocephalus have symptoms similar to PD as part of their clinical presentation.[1] Unless otherwise stated, all references to PD in this chapter refer to the idiopathic type.

The age at onset of PD is variable, usually between 50 and 80 years, with a mean onset of 55 years.[2] Both the incidence and prevalence of PD are age-dependent, with annual incidence estimates ranging from 10 cases/100,000 (age 50–59 years) to 100 cases/100,000 (age 80–89 years) and an estimated prevalence of 1% of the population older than 65 years of age.[3],[4] Men are affected slightly more frequently than women.[3] Despite the availability of effective symptomatic treatments to improve both quality of life and life expectancy, no cure exists. The symptoms of PD are progressive, and within 10 to 20 years, significant immobility results for most patients.[5] More rapid rates of symptom progression and motor disability have been observed in patients of older age at disease onset.[6] PD itself does not cause death; however, patients often succumb to complications related to impaired mobility and function (e.g., aspiration pneumonia, thromboembolism) and overall frailty.[5]

Etiology

The etiology of PD is poorly understood. Most evidence suggests it is multifactorial and attributable to a complex interplay between age-related changes in the nigrostriatal tract, underlying genetic risks, and/or environmental triggers. Support for this hypothesis can be found in several historic observations. Notably, the postviral parkinsonian symptoms occurring after epidemics of encephalitis in the early 1900s, and the discovery that ingestion of a meperidine analog, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), by heroin addicts in northern California during the early 1980s caused a rapid and irreversible parkinsonism via the oxidation of free radicals during metabolism by the MAO-B enzyme.[7]

For an excellent in-depth discussion of the importance of the MPTP discovery and its influence on PD research, please view the episode “My Father, My Brother, and Me” from the Public Broadcasting System program Frontline at http://www.pbs.org/wgbh/pages/frontline/parkinsons/.

The relative contributions of environment and genetics to the occurrence of PD remain controversial; rural living, pesticide exposure, and consumption of well water have consistently been associated with increased lifetime risk of PD, whereas cigarette smoking and caffeine ingestion appear to be protective.[8] Mutations in several genes, including α-synuclein (SNCA), leucine-rich repeat kinase-2 (LRRK2), parkin, PTEN- induced kinase-1 (PINK1), and DJ-1, have been observed in rare familial inherited cases of PD, but these genes lack typical Mendelian patterns of inheritance, and do not account for the threefold increased risk of developing PD for individuals who have a first-degree relative affected with sporadic PD.[9] Recent advances in molecular genetics and genome-wide association studies have revealed other novel risk genes; however, the exact linkage between genetics, environment, and clinical expression of disease remains uncertain.[10]

Pathophysiology

The salient features of PD result from a loss of dopaminergic neurons in the nigrostriatal tracts of the brain and development of abnormal intraneuronal protein aggregates called Lewy bodies that interfere with neuronal function. The nigrostriatal tracts are neuronal tracts between the substantia nigra and the striatum. They are part of the extrapyramidal system of the brain involving the basal ganglia. This area is involved with maintaining posture and muscle tone by regulating voluntary smooth muscle activity. The pigmented neurons within the basal ganglia have dopaminergic fibers, and in PD, these dopamine-producing neurons are progressively depigmented. The remaining dopaminergic-producing cells have been shown (in postmortem examination) to contain Lewy bodies.[11] Lewy body pathology appears to ascend the brain in a predictable manner in PD, beginning in the medulla oblongata in preclinical stages (which may explain observations of anxiety, depression, and olfactory disturbance), ascending to the midbrain (motor dysfunction), and spreading eventually to the cortex (cognitive and behavioral changes).[12] The loss of dopamine neurons, either from death or from dysfunction, results in loss of dopamine-mediated inhibition of acetylcholine neurons. In PD, the typical balance of dopamine and acetylcholine is lost, resulting in a relative increase in cholinergic activity.

The exact pathologic sequence leading to neurodegeneration is unclear, but free radicals formed as by-products of dopamine auto-oxidation have been implicated. The finding that a critical threshold of neuronal loss (at least 70%–80%) occurs before PD becomes clinically apparent suggests that adaptive mechanisms (e.g., upregulation of dopamine synthesis or downregulation of synaptic dopamine reuptake) may somehow influence disease progression during the preclinical stages.

Clinical Presentation of Parkinson’s Disease

CASE 59-1

QUESTION 1: L.M., a 55-year-old, right-handed male artist, presents to the neurology clinic complaining of difficulty painting because of unsteadiness in his right hand. On questioning, he notes that it is becoming increasingly difficult to get out of chairs after sitting for a long period because of tightness in his arms and legs. He also reports having a loss in sense of smell. His medical history is significant for gout (currently requiring no treatment), constipation, benign prostatic hypertrophy, and aortic stenosis. He does not smoke, but usually drinks one alcoholic beverage in the evenings. His only prescription medication is citalopram 10 mg by mouth once daily. On physical examination, L.M. is noted to be a well-developed, well-nourished man who displays a notable lack of normal changes in facial expression and speaks in a soft, monotone voice. Examination of his extremities reveals a slight ratchetlike rigidity in both arms and legs, and a mild resting tremor is present in his right hand. His gait is slow but otherwise normal, with a slightly bent posture. His balance is determined to be normal, with no retropulsion or loss of righting reflexes after physical threat. His genitourinary examination is remarkable only for prostatic enlargement. The remainder of his physical examination is within normal limits. Laboratory values and vital signs obtained at this visit include the following:

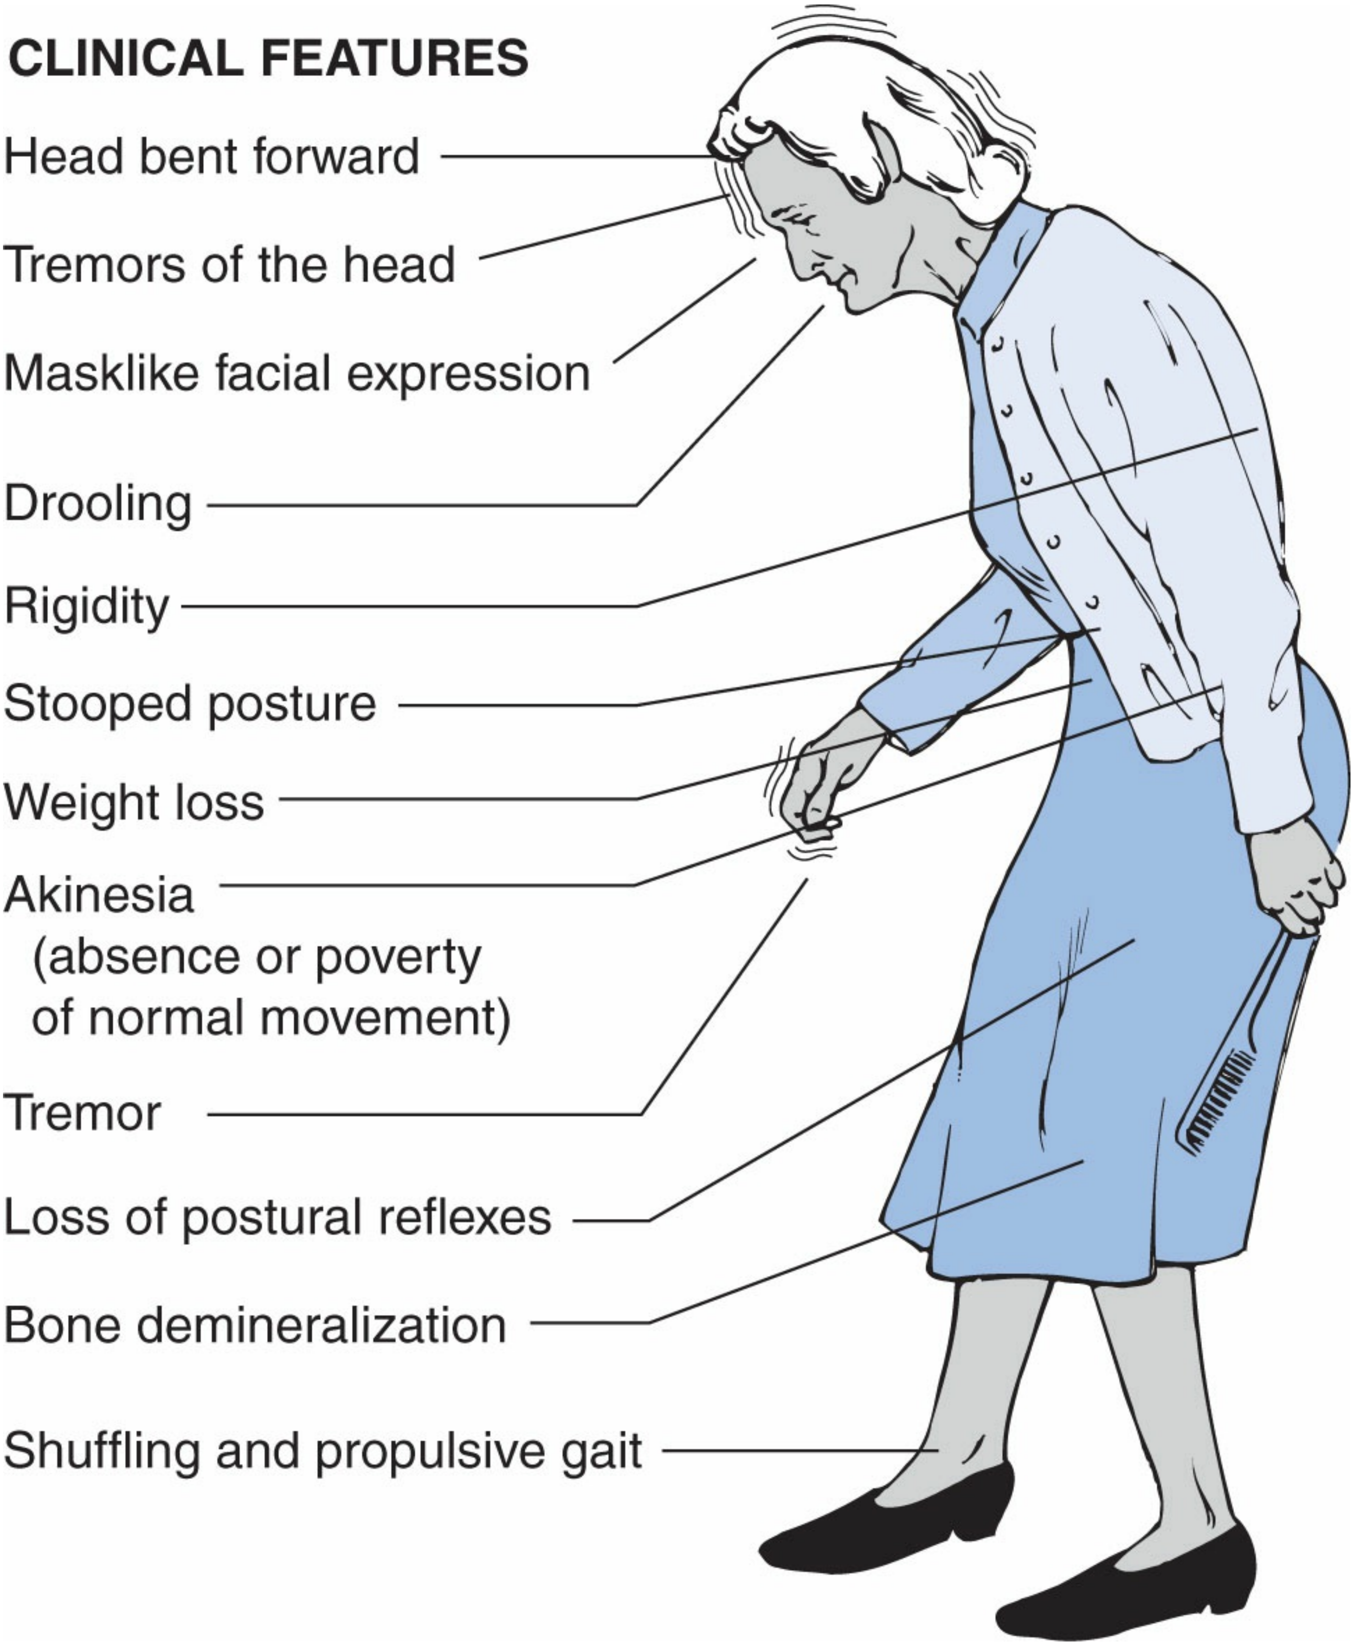
Blood pressure, 119/66 mm Hg

Heart rate, 71 beats/minute
Sodium, 132 mEq/L
Potassium, 4.4 mEq/L
Blood urea nitrogen, 19 mg/dL
Creatinine, 1.1 mg/dL
Thyroid stimulating hormone, 3.65 microunits/L
Vitamin B12, 612 pg/mL
Folate, 5.2 ng/mL
White blood cells, 4,400 cells/μL
Red blood cells, 5.9×10^6/μL
Hemoglobin, 13.8 g/dL
Hematocrit, 41%
Uric acid, 6.3 mg/dL

How is PD diagnosed? Is neuroimaging or any other testing helpful in establishing the diagnosis of PD? What signs and symptoms suggestive of PD are present in L.M., and which of these symptoms are among the classic symptoms for diagnosing PD?

The foundation for establishing the diagnosis of PD remains firmly grounded in obtaining a careful history and physical examination.[11] The neurologic examination to assess motor function, along with a positive response to levodopa, is highly diagnostic. The search for biomarkers of premotor PD in blood, cerebrospinal fluid, and urine has not uncovered single, practical candidates that are sensitive and specific.[9] Likewise, although imaging techniques can visualize nigrostriatal nerve terminals of dopamine synthesis and identify presymptomatic pathology, their use remains investigational, and routine use in asymptomatic, at-risk individuals is not yet justified. Other associated premotor symptoms, such as hyposmia (a reduced ability to smell and detect odors), rapid eye movement (REM) sleep disorder, and softening and tonal changes of the voice are among the earliest symptoms to appear; screening for these findings may prove more economically practical in identifying a high risk population worthy of further diagnostic evaluation.[13] With further scientific advancements, the diagnosis of PD may rely on clinical, imaging, genetic, and a panel of laboratory biomarker data. However, by the time patients such as L.M. present with symptoms, a substantial burden of neuropathologic evidence has accumulated, and therefore, a diagnosis can be made clinically, without the need for further laboratory or radiologic testing.

The classic features of PD—tremor, limb rigidity, and bradykinesia—are easily recognized, particularly in advanced stages of disease. Limb rigidity and bradykinesia are direct consequences of dopamine loss; by disinhibiting cholinergic transmission, dopamine loss indirectly causes tremor. It is important to note that not all classic features are required to make the diagnosis of PD. The presence of two or more features indicates clinically probable PD.[14] Tremor, which is most often the first symptom observed in younger patients, is usually unilateral on initial presentation. Frequently, the low-amplitude tremor is of a pill-rolling type involving the thumb and index finger (3–6 Hz); it is present at rest, worsens under fatigue or stress, and is absent with purposeful movement or when asleep.[1] These features help distinguish it from essential tremor, which usually manifests as a symmetric tremor in the hands, often accompanied by head and voice tremor.[11] Approximately 20% of patients with PD do not present with tremor.[11] Muscular rigidity resulting from increased muscle tone often manifests as a cogwheel or ratchet (catch-release) type of motion when an extremity is moved passively.[1] Rigidity may also be experienced as stiffness or vague aching or limb discomfort.[11] Bradykinesia refers to an overall slowness in initiating movement. Early in the disease, patients may describe this as weakness or clumsiness of a hand or leg.[11] Because the disease progresses, difficulty initiating and terminating steps results in a hurried or festinating gait; the posture becomes stooped (simian posture), and postural reflexes are impaired.[1] Symptoms that were unilateral on initial presentation progress asymmetrically and often become bilateral and more severe with disease progression.[1] Patients with PD may develop masked facies, or a blank stare with reduced eye blinking (Figure 59-1).



CLINICAL FEATURES
Head bent forward
Tremors of the head
Masklike facial expression
Drooling
Rigidity
Stooped posture
Weight loss
Akinesia (absence or poverty of normal movement)
Tremor
Loss of postural reflexes
Bone demineralization
Shuffling and propulsive gait

Figure 59-1 Clinical features of Parkinson's disease. (Reprinted with permission from Rosdahl CB. Book of Basic Nursing. 7th ed. Philadelphia, PA: Lippincott-Raven; 1999:1063.)

Because the diagnosis of PD is clinical, misdiagnosis can occur, leading to inappropriate, ineffective, or delayed treatment. Several conditions can be mistaken for PD and are important to distinguish from PD because they respond poorly to dopaminergic medications and are associated with worse prognosis.[11] Falls or dementia early in the disease, symmetric parkinsonism, wide-based gait, abnormal eye movements, marked orthostatic hypotension, urinary retention, or marked disability within 5 years after the onset of symptoms suggests alternative diagnoses to PD.[11] Drugs may also mimic idiopathic PD. Drugs that act as antagonists at dopaminergic D_2 receptors (e.g., neuroleptics, prochlorperazine, and metoclopramide), and others such as valproate, amiodarone, phenytoin, and lithium may cause a state of drug-induced parkinsonism. This should be excluded before the diagnosis of PD is established. Although generally reversible, symptoms may persist for weeks or months after discontinuation of the offending agent.[11]

L.M. initially presents with classic premotor features such as his soft, monotone voice and reduced sense of smell, in addition to classic symptoms of PD. A noticeable unilateral resting tremor is present along with decreased manual dexterity, as evidenced by his difficulty handling a paintbrush. Handwriting abnormalities occur frequently, particularly micrographia, a symptom of bradykinesia. Because L.M. is an artist, this abnormality would be particularly troublesome. Rigidity (ratcheting of the arms) and a mask-like facial expression also are present. Although he has a partially stooped posture, it is difficult to attribute this entirely to the disease because postural changes commonly occur with advancing age and, on physical examination, his balance was normal. To confirm the diagnosis of PD, a therapeutic trial of medication (levodopa) may be considered. A positive response to levodopa, as evidenced by an improvement in motor function, suggests the diagnosis of PD. However, patients with the tremor-predominant form of the disease may not respond to levodopa, especially in the early stages of the disease.[11]

Staging of Parkinson’s Disease

CASE 59-1, QUESTION 2: What are the stages of PD? In what stage of the disease is L.M.?

To assess the degree of disability and determine the rate of disease progression relative to treatment, various scales have been developed. The most common of these is the Hoehn and Yahr scale (Table 59-1).[2] In general, patients in Hoehn and Yahr[2] stage 1 or 2 of PD have mild disease that does not interfere with activities of daily living (ADLs) or work and usually requires minimal or no treatment. In stage 3 disease, daily activities are restricted and employment may be significantly affected unless effective treatment is initiated. According to the scale, L.M. appears to be in late stage 2, early stage 3 of the disease.

With advanced-stage disease (3, 4), most patients require a double or triple drug therapy strategy. Patients with end-stage disease (stage 5) are severely incapacitated and, because of advanced disease progression, often do not respond well to drug therapy.

Treatment of Parkinson's Disease

OVERVIEW OF THERAPY

Numerous national and international guidelines exist regarding the management of motor and nonmotor symptoms of PD. These guidelines include the American Academy of Neurology (AAN) Practice Parameters developed in 2002 and 2006,[15],[16] the United Kingdom National Institute for Health and Care Excellence (NICE) National Guideline developed in 2006 and revised in July 2017,[17] and the European Federation of Neurological Societies Movement Disorder Society-European Section (EFNS MDS-ES) Guidelines developed in 2013[18]; all are cited throughout the text.

Table 59-1

Staging of Disability in Parkinson's Disease (PD)

Stage 1	Unilateral involvement only; minimal or no functional impairment
Stage 2	Bilateral involvement, without impairment of balance
Stage 3	Evidence of postural imbalance; some restriction in activities; capable of leading independent life; mild-to-moderate disability
Stage 4	Severely disabled, cannot walk and stand unassisted; significantly incapacitated
Stage 5	Restricted to bed or wheelchair unless aided

Although most of this chapter is devoted to the drug therapy of PD, the importance of nonpharmacologic, supportive care cannot be overemphasized. Exercise, physical and occupational therapy, and good nutritional support can be beneficial at the earlier stages to improve mobility, increase strength, and enhance well-being and mood.[17] Psychological support is often necessary in dealing with depression and other related problems. Newly diagnosed patients and their family members need to be educated about what to expect from the disease and the various forms of treatment available. The support of family members is vital in establishing an overall effective therapeutic plan.

Nonpharmacologic therapy should continue throughout the course of care; however, due to the progressive nature of PD, pharmacologic therapy is often necessary. Because the salient pathophysiologic feature of PD is the progressive loss of dopamine from the nigrostriatal tracts in the brain, drug therapy for the disease is aimed primarily at replenishing the supply of dopamine. This is accomplished through one, or a combination, of the following methods: (a) administering exogenous dopamine in the form of a precursor, levodopa; (b) stimulating dopamine receptors within the striatum through the use of dopamine agonists (e.g., pramipexole, ropinirole); or (c) inhibiting the major metabolic pathways within the brain that are responsible for the degradation of levodopa and its metabolites. This latter effect is achieved through the use of aromatic L-amino acid decarboxylase (AAD) inhibitors (e.g., carbidopa), COMT inhibitors (e.g., entacapone), or MAO-B inhibitors (e.g., selegiline, rasagiline). Anticholinergics are also used; however, they are solely efficacious for the cholinergic-mediated tremor, and their routine use is limited by central nervous system (CNS) adverse effects, particularly in older patients. A unique agent, amantadine, is also used occasionally and may provide modest benefits via both dopaminergic and nondopaminergic (inhibition of glutamate) mechanisms (Table 59-2). Because PD progresses, additional options, such as surgery, may be appropriate for a subset of patients.

Despite optimization of both pharmacologic and nonpharmacologic therapies in PD, physical disability is progressive and unavoidable. In many instances, adverse effects of the medications themselves can lead to additional problems. These include neuropsychiatric problems (e.g., cognitive impairment and dementia, hallucinations and delirium, depression, agitation, anxiety), autonomic dysfunction (e.g., constipation, urinary problems, sexual problems, orthostasis, thermoregulatory imbalances), falls, sleep disorders (e.g., insomnia or sleep fragmentation, nightmares, RLS), and motor complications (e.g., disabling periods of either too much [dyskinetic] or too little [akinetic] dopaminergic activity). In general, the more efficacious medications are also those with the greatest risk of serious side effects and motor complications.

Table 59-2

Medications Used for the Treatment of Parkinson's Disease (PD)

Generic (Trade) Name	Dosage Unit	Titration Schedule	Usual Daily Dose	Adverse Effects
Amantadine (Symmetrel)	100-mg capsule and tablet Liquid: 50 mg/5 mL	100 mg every day; increased by 100 mg every 1–2 weeks	100–300 mg	Orthostatic hypotension, insomnia, depression, hallucinations, livedo reticularis, xerostomia
Anticholinergic Agents				
Benztropine (Cogentin)	0.5-, 1-, and 2-mg tablets Injection: 1 mg/mL	0.5 mg every day increased by 0.5 mg every 5–6 days	1–3 mg given every day to BID	Constipation, xerostomia, dry skin, dysphagia, confusion, memory impairment
Trihexyphenidyl (Artane)	2- and 5-mg tablets Liquid: 2 mg/5 mL	1–2 mg/day increased by 1–2 mg every 3–5 days	6–15 mg divided TID to QID	Constipation, xerostomia, dry skin, dysphagia, confusion, memory impairment
Combination Agents				

Carbidopa–levodopa (immediate release)/entacapone (Stalevo)	12.5-/50-/200-, 18.75-/75-/200-, 25-/100-/200-, 31.25-/125-/200-, 37.5-/150-/200-, 50-/200-/200-mg tablets	Titrate with individual dosage forms (carbidopa/levodopa and entacapone) first, then switch to combination tablet	Varies (see individual drugs)	See individual drugs
Dopamine Replacement				
Carbidopa–levodopa (regular) (Sinemet)	10-/100-, 25-/100-, and 25-/250-mg tablets	25/100 mg BID, increased by 25/100 mg weekly to effect and as tolerated	30/300 to 150/1,500 mg divided TID to QID	Nausea, orthostatic hypotension, confusion, dizziness, hallucinations, dyskinesias, blepharospasm
Carbidopa–levodopa (CR) (Sinemet CR)	25-/100- and 50-/200-mg tablets	25/100 mg BID (spaced at least 6 hours apart), increased every 3–7 days	50/200 to 500/2,000 divided QID	Same as regular Sinemet
Carbidopa–levodopa (ER) (Rytary)	23.75-/95-, 36.25-/145-, 48.75-/195-, 61.25-/245-mg capsules	23.75/95 mg TID; may increase to 36.25/145 mg TID on day 4 and titrate to response	Variable	Same as regular Sinemet
Carbidopa–levodopa (enteral suspension) (Duopa)	4.63-/20-mg/mL in 100-mL cassette	Total daily dose administered over 16 hours	Variable	Same as regular Sinemet
Carbidopa–levodopa ODT (Parcopa)	10-/100-, 25-/100-, and 25-/250-mg tablets	25/100 TID, increased every 1–2 days; if transferring from regular levodopa <1,500 mg/day, start 25/100 mg TID to QID (start 25/250 mg TID to QID if already on >1,500 mg/day of regular levodopa)	25/100 to 200/2,000 divided TID to QID	Same as regular Sinemet; may occur more rapidly than with regular Sinemet
Dopamine Agonists				
Bromocriptine (Parlodel)	2.5-mg tablet, 5-mg capsule	1.25 mg BID, titrate slowly as tolerated (2.5 mg/day every 2-4 weeks)	10–40 mg divided TID; Max 100 mg/day	Orthostatic hypotension, confusion, dizziness, hallucinations, nausea, muscle cramps; retroperitoneal, pleural, pericardial fibrosis; cardiac valve thickening
Pramipexole (Mirapex, Mirapex	Immediate release: 0.125-, 0.25-, 0.50-,	Immediate release: 0.375 mg divided	Immediate release: 1.5–4.5 mg divided	Orthostatic hypotension,

ER)	0.75-, 1-, 1.5-mg tablets ER: 0.375-, 0.75-, 1.5-, 2.25-, 3-, 3.75-, 4.5-mg tablets	TID; titrate weekly by 0.125–0.25 mg/dose ER: 0.375 mg once daily; titrate weekly by 0.75 mg/dose	TID ER: 1.5–4.5 mg once daily	confusion, dizziness, hallucinations, nausea, somnolence
Ropinirole (Requip, Requip XL)	0.25-, 0.5-, 1-, 2-, 3-, 4-, 5-mg tablet XL: 2-, 4-, 6-, 8-, 12-mg tablets	0.25 mg TID; titrate weekly by 0.25 mg/dose XL: 2 mg once daily; titrate weekly by 2 mg/day	3–12 mg divided TID XL: 3–12 mg once daily	Orthostatic hypotension, confusion, dizziness, hallucinations, nausea, somnolence

Apomorphine (Apokyn)	10 mg/mL injection	Initial 2-mg subcutaneous test dose; begin with 2 mg; increase by 1 mg every few days	2–6 mg TID	Orthostatic hypotension, drowsiness, yawning, injection site reactions, nausea, vomiting (administer with trimethobenzamide, not 5-hydroxytryptamine-3 [5-HT_3] antagonists)
Rotigotine (Neupro)	1,-, 2-, 3-, 4-, 6-, 8-mg/24 hour transdermal delivery system	Early stage: 2 mg/24 hour; Advanced stage: 4 mg/24 hour; titrate weekly by 2 mg/24 hour; Application site should be rotated daily between abdomen, thigh, hip, flank, shoulder, or upper arm and do not use same site within 14 days	4–6 mg/24 hour	Hallucinations, nausea, vomiting, anorexia, somnolence, insomnia, dizziness, hyperhidrosis, visual disturbance, peripheral edema, and application site reactions; avoid in patients with known sulfite sensitivity
COMT Inhibitors				
Entacapone (Comtan)	200-mg tablet	200 mg with each administration of carbidopa/levodopa, up to 8 tablets daily	3–8 tablets daily	Diarrhea, dyskinesias, abdominal pain, urine discoloration
Tolcapone (Tasmar)	100-mg tablet	100 mg TID	300–600 mg divided TID	Diarrhea, dyskinesias, abdominal pain, urine discoloration, hepatotoxicity
Monoamine Oxidase Type B (MAO-B) Inhibitors				

Selegiline (Eldepryl)[a]	5-mg tablet, capsule	5 mg every morning; may increase to 5 mg BID (5 mg with breakfast and 5 mg with lunch)	5–10 mg/day	Insomnia, dizziness, nausea, vomiting, xerostomia, dyskinesias, mood changes; use caution when coadministered with sympathomimetics or serotoninergic agents (increased risk of serotonin syndrome); avoid tyramine-containing foods
Selegiline ODT (Zelapar)	1.25-mg tablet	1.25 mg every day; avoid food or liquids for 5 minutes before and after administration; may increase to 2.5 mg every day after 6 weeks	1.25–2.5 mg every day	Insomnia, dizziness, nausea, vomiting, xerostomia, dyskinesias, mood changes; use caution when coadministered with sympathomimetics or serotoninergic agents (increased risk of serotonin syndrome); avoid tyramine-containing foods
Rasagiline (Azilect)	0.5-, 1-mg tablets	0.5–1 mg once daily	0.5–1 mg/day	Similar to selegiline
Safinamide (Xadago)[b]	50-, 100 mg tablets	50 mg once daily; dose may be increased after two weeks to 100 mg once daily	50-100 mg/day	Similar to selegiline

[a] A transdermal formulation is also available, but not approved for use in PD.

[b] Approved only for use as adjunctive treatment to levodopa/carbidopa in patients experiencing “off” episodes.

BID, twice daily; COMT, catechol-O-methyltransferase; MAO-B, monoamine oxidase type B; ODT, orally disintegrating tablet; QID, four times daily; TID, three times daily.

Treatment of Early Parkinson’s Disease

CASE 59-1, QUESTION 3: When should L.M. begin treatment for his PD?

In choosing when to treat the symptoms of PD and which therapy to use, care must be taken to approach each patient individually. Although no consensus has been reached about when to initiate symptomatic treatment, most healthcare professionals agree that treatment should begin when the patient begins to experience functional impairment as defined by (a) threat to employment status, (b) symptoms affecting the dominant side of the body, or (c) bradykinesia or rigidity.[19],[20] Individual patient preferences also should be considered. Judging by the symptoms L.M. is displaying, he would likely benefit from immediate treatment. His symptoms are unilateral but are occurring on his dominant side and are interfering with his ability to paint, thus affecting his livelihood. He is also showing signs of rigidity and bradykinesia but can otherwise live independently. An algorithm for the management of patients with early PD is presented in Figure 59-2. The long-term, individualized treatment plan is usually characterized by frequent dosage adjustments because of the chronic and progressive nature of the disease.

CASE 59-1, QUESTION 4: The decision is made to begin drug therapy for L.M. Should therapy be initiated with a levodopa or levodopa-sparing therapy?

Despite advances in pharmacologic treatment options for PD, no therapy has been proven to be disease-modifying or neuroprotective. Therapy continues to be symptomatic, and levodopa remains the most effective antiparkinsonian agent.[11] However, the question of when to begin levodopa in the treatment of PD has been historically debated. With long-term use, the efficacy of levodopa decreases and risk for the development of motor fluctuations and dyskinesias increases. Because escalating doses of levodopa are accompanied by a high frequency of undesirable side effects, other methods of enriching dopamine supply have been developed. Two such methods include the use of dopamine agonists and MAO-B inhibitors. Both of these modalities have proven efficacy early in the disease.[17]

Dopamine agonists, which bind directly to dopamine receptors, do not require metabolic conversion to an active product and therefore act independently of degenerating dopaminergic neurons. In clinical trials comparing dopamine agonists with levodopa, ADLs and motor features are improved to a greater degree with levodopa compared with dopamine agonists.[18] Although they are not as effective as levodopa, the dopamine agonists have potential advantages. Unlike levodopa, circulating plasma amino acids do not compete with dopamine agonists for absorption and transport into the brain, eliminating administration constraints. Dopamine agonists have a longer half-life than levodopa formulations, reducing the need for multiple daily dosing. As a class, dopamine agonists provide adequate control of symptoms when given as monotherapy in up to 80% of patients with early-stage disease.[21]

Short- and long-term comparisons of patients with early disease started on either levodopa or dopamine agonists have varying results. In trials extending 4 to 5 years, therapy with dopamine agonists is associated with fewer motor complications such as dyskinesias, delayed time to dyskinesias, and delayed need for initiation of dopaminergic therapy.[22–24] Against levodopa as initial therapy, early trials of the dopamine agonists appear to delay the onset of dyskinesias. In a randomized, controlled trial evaluating the development of motor complications with levodopa or the dopamine agonist pramipexole, 301 untreated patients with early PD were randomly assigned to receive either pramipexole 0.5 mg 3 times daily or carbidopa/levodopa 25/100 mg 3 times daily.[24] Patients in both arms could be prescribed open-label levodopa as needed for disability during the maintenance phase of the study. After a mean follow-up of 24 months, fewer pramipexole-treated patients reached the primary endpoint of time to the first occurrence of wearing-off, dyskinesias, or on–off motor fluctuations (28% vs. 51%; $P<0.001$) than the patients initially randomly assigned to levodopa therapy. Additionally, patients in the pramipexole group were receiving lower daily doses of levodopa, theoretically conferring a reduced risk of developing motor complications. Long-term follow-up of this cohort (mean = 6 years) revealed a persistently lower rate of dopaminergic motor complications in the pramipexole-treated patients compared with those receiving levodopa (50% vs. 68.4%, respectively; $P = 0.002$).[25]

Motor Complications

Figure 59-2 Suggested treatment algorithm for the management of early PD.

Despite the continued increased risk of motor complications in patients started on levodopa, trials extending 10 to 15 years found no significant difference in disease severity rating or rates of disabling dyskinesias.[26],[27] Patients treated initially with ropinirole were less likely to experience dyskinesias compared with those treated initially with levodopa at the end of a 5-year evaluation.[22] Patients in the ropinirole group used lower mean daily doses of levodopa (427 mg vs. 753 mg) but were almost twice as likely to need open-label levodopa supplementation (66% vs. 36%). Dyskinesias developed in 20% of the ropinirole-treated patients compared with 45% of the levodopa-treated patients. For ropinirole-treated patients who were able to remain on monotherapy without open-label levodopa supplementation, only 5% experienced dyskinesia, compared with 36% of those receiving levodopa monotherapy. Although the lower incidence of dyskinesias was shown to persist in a long-term open-label follow-up of this study cohort, there was no difference in disease severity between the ropinirole-treated group and the levodopa-treated group at 10 years.[26] There may be additional trends toward better cognitive and health-related quality of life outcomes in the patients started on levodopa.[27] This may be due in part to the fact that although dopamine agonists do delay motor complications, they are not without side effects. Trials have consistently shown higher rates of adverse drug reactions in patients initially started on dopamine agonists.[22],[25] One open-label, randomized trial found that 28% of patients discontinued initial therapy with dopamine agonists due to side effects versus only 2% of patients initially given levodopa.[28] Regardless of initial therapy chosen, due to disease progression, levodopa therapy will eventually be required, motor complications will develop, and disability will be present.

MAO-B inhibitors are an alternative method of enriching dopamine supply in early disease. These agents increase nigrostriatal dopamine supply via the irreversible inhibition of MAO-B, a major enzymatic pathway responsible for the metabolism of dopamine in the brain, and require the presence of dopamine for clinical effect.[29] Though MAO-B inhibitors have been shown to delay the need for dopaminergic therapy with levodopa, definitive efficacy comparisons are lacking.[29]

Early guidance from the AAN supported either dopamine agonists or levodopa as initial therapy for PD; more recent NICE and EFNS MDS-ES guidelines additionally support the use of MAO-B inhibitors in initial therapy.[15],[17],[18] The long-term effectiveness of dopamine agonists and MAO-B inhibitors compared with levodopa as initial treatment for PD (PD MED) trial set out to compare and contrast levodopa versus levodopa-sparing therapies.[28] Patients assigned to monotherapy with MAO-B inhibitors or dopamine agonists were generally younger and healthier than those assigned levodopa as initial therapy. At 7-year follow-up, 72% of patients initially assigned to MAO-B inhibitors withdrew from initial therapy and changed treatment compared to 50% in the dopamine agonist group and 7% in the levodopa group (P<0.0001). Among those patients initiated on MOA-B inhibitors, 48% withdrew due to side effects and 36% withdrew due to lack of efficacy, and for patients initiated on dopamine agonists, 82% withdrew due to side effects and 16% withdrew due to lack of efficacy.[28] As shown in prior studies, levodopa improved function and quality of life to a greater degree; however, the primary mobility outcome did not reach the prespecified minimally important difference. Mobility scores were not significantly different between MAO-B inhibitors and dopamine agonists indicating that MAO-B inhibitors are at least as effective as dopamine agonists in early therapy of PD.[28] Additionally, at 7 years, patients on dopamine agonists were on the highest overall amount of medication. The study confirms that initial treatment with a dopamine agonist, MAO-B inhibitor, or levodopa may all be reasonable approaches.

Disease severity, degree of functional impairment, life expectancy, and age guide therapeutic drug selection in early PD. In younger patients (e.g., age <65 years) with milder disease, such as L.M., the initiation of levodopa-sparing therapy with either a dopamine agonist or MAO-B inhibitor would be appropriate. Initiating levodopa therapy later in the course of PD delays the development of motor complications, particularly the troubling peak-dose, levodopa-induced dyskinesias, which eventually develop with advancing PD. Patients with younger age at disease onset, such as L.M., may be at an increased lifetime risk of developing dyskinesias.[19] Although the PD MED trial did conclude that MAO-B inhibitors are at least as effective as dopamine agonists for initial therapy, other meta-analyses show that the degree of symptomatic benefit over placebo is small in comparison with those of dopamine agonists over placebo.[30] Overall, there is a lack of comparative data between MAO-B inhibitors and dopamine agonists. Therefore, use of MAO-B inhibitors in initial therapy is often limited to young patients with more mild functional impairments. In older patients (e.g., age >65 years), those with more significant functional impairments, or those with limited life expectancy, use of levodopa may be warranted, as a result of the large number of symptomatic benefits associated with its use despite the relatively high risk of motor complications and side effects. Additionally, levodopa may be more appropriate initial treatment in older patients, because they may be more likely to experience intolerable CNS side effects from dopamine agonists and less likely to develop motor complications over their lifetime.[19]

In the case of L.M., his relatively young age, mild disease, and moderate functional impairments make him a good candidate for initial therapy with a dopamine agonist. L.M. will require levodopa therapy at a later time, when he reaches more advanced stages of the disease. By initiating therapy first with a dopamine agonist, rescue levodopa therapy can likely be started at smaller doses, and the onset of motor complications that often occur with escalating doses and extended therapy with levodopa may be delayed.

DOPAMINE AGONISTS

CASE 59-1, QUESTION 5: L.M. is to be started on a dopamine agonist. Which agent should be selected?

Table 59-3

Pharmacologic and Pharmacokinetic Properties of Dopamine Agonists

	Bromocriptine	**Pramipexole**	**Ropinirole**	**Apomorphine**	**Rotigotine**
Type of compound	Ergot derivative	Nonergoline	Nonergoline	Nonergoline	Nonergoline
Receptor specificity	D_2, D_1,[a] α_1, α_2, 5-HT	D_2, D_3, D_4, α_2	D_2, D_3, D_4	D_1, D_2, D_3, D_4, D_5, α_1, α_2, 5-HT_1, 5-HT_2	D_1, D_2, D_3, 5-HT_1
Bioavailability	7% (first-pass metabolism)	90%	55% (first-pass metabolism)	<5% orally; 100% subcutaneous	NA
T_{max} (minutes)	70–100	60–180	90	10–60	15–18 (hours); no characteristic peak observed
Protein binding	90%–96%	15%	10%–40%	>99.9%	89.5%

Half-life (hours)	2–8	8–12	6	0.5–1	3–7

[a] Antagonist.

5-HT, serotonin; NA, not applicable.

Two generations of dopamine agonists have been used for the treatment of idiopathic PD, in early-stage PD as monotherapy, or as an adjunct to levodopa in patients with advanced disease. The comparative pharmacologic and pharmacokinetic properties of these agents are shown in Table 59-3. The first-generation dopamine agonists, which are derived from ergot alkaloids, include bromocriptine, pergolide, and cabergoline. These older agents are now rarely used because of increased risk of retroperitoneal, pleural, and pericardial fibrosis, as well as a two- to fourfold increased risk for cardiac valve fibrosis when compared with nonergoline dopamine agonists and controls.[31,32] Pergolide was voluntarily withdrawn in the United States (US) in 2007 for this reason, and although cabergoline continues to be used in Europe, it is only indicated in the United States for the treatment of hyperprolactinemia. Pramipexole, ropinirole, apomorphine, and rotigotine are second-generation nonergoline dopamine agonists. Of these agents, pramipexole and ropinirole are commonly prescribed. Apomorphine is available only in injectable form, for use as a rescue agent in the treatment of hypomobility "off" episodes in patients with PD. Rotigotine, a once-daily transdermal formulation, was recently re-introduced to the market.

Dopamine agonists work by directly stimulating postsynaptic dopamine receptors within the striatum. The two families of dopamine receptors are D_1 and D_2. The D_1-like receptor family includes the D_1 and D_5 dopamine subtype receptors and the D_2-like receptor family includes D_2, D_3, and D_4 dopamine subtype receptors. Stimulation of D_2 receptors is largely responsible for reducing rigidity and bradykinesia, whereas the precise role of the D_1 receptors remains uncertain.[33] Pramipexole and ropinirole exhibit selectivity for D_2 receptors without any significant affinity for D_1 receptors whereas rotigotine has activity at all dopamine receptors.[34–36] Although the dopamine agonists differ slightly from each other in terms of their affinities for dopamine receptor subtypes, these agents produce similar clinical effects when used to treat PD, and no compelling evidence favors one agent over another strictly on efficacy measures. Instead, experience with the nonergoline dopamine agonists, specifically pramipexole and ropinirole, makes them currently preferred as initial dopamine agonists. Thus, either agent would be acceptable as initial therapy in L.M.

CASE 59-1, QUESTION 6: The decision is made to begin pramipexole in L.M. How effective is pramipexole in the initial treatment of PD? How does ropinirole compare?

Pramipexole

Pramipexole has been well studied as monotherapy in patients with early-stage PD and as an adjunct to levodopa therapy in advanced-stage disease.[34–36] These trials were multicenter, placebo-controlled, parallel-group studies, and parts of the Unified Parkinson's Disease Rating Scale (UPDRS) were used as the primary outcome measures, specifically improvement in ADLs (Part II) and motor function scores (Part III). Each evaluation on the UPDRS is rated on a scale of 0 (normal) to 4 (can barely perform). Lower scores on the UPDRS after treatment indicate an improvement in overall performance.

To view the UPDRS and other assessment tools for the symptoms of Parkinson's disease, please visit **http://www.movementdisorders.org/MDS/Education/Rating-Scales.htm**.

The evidence for the efficacy of pramipexole in early PD comes from two large-scale, double-blind, placebo-controlled studies that included a total of 599 patients with early-stage PD (mean disease duration of 2 years).[35],[36] In the first study, 264 patients were randomly assigned to receive one of four fixed doses (1.5, 3, 4.5, or 6 mg/day) or placebo.[35] The pramipexole-treated patients had a 20% reduction in their total UPDRS scores compared with baseline values, whereas no significant improvement was observed in the placebo-treated patients. A trend toward decreased tolerability was noted because the pramipexole dosage was escalated, especially in the 6 mg/day group. A second study of 335 patients titrated doses up to the maximal tolerated dose (not to exceed 4.5 mg/day) and then followed patients for a 6-month maintenance phase.[36] The mean pramipexole maintenance dosage was 3.8 mg/day. Those treated with pramipexole experienced significant improvements in both the ADL scores (22%–29%; $P<0.0001$) and motor scores (25%–31%; $P<0.0001$), whereas there were no significant changes in the placebo group.

Ropinirole

Similar to pramipexole, ropinirole is a synthetic nonergoline dopamine agonist. Although the drug is pharmacologically similar to pramipexole, it has some distinct pharmacokinetic properties (Table 59-3). Unlike pramipexole, which is primarily eliminated by renal excretion, ropinirole is hepatically metabolized and undergoes significant first-pass hepatic metabolism.[37] Similar to

---

pramipexole, ropinirole is approved for use as monotherapy in early-stage idiopathic PD and as an adjunct to levodopa therapy in patients with advanced-stage disease.

Ropinirole has not been directly compared with pramipexole in randomized, double-blind comparisons, but it appears to have comparable efficacy in indirect comparison. In several randomized, double-blind, multicenter, parallel-group studies comparing ropinirole with placebo, bromocriptine, or levodopa, 6 months of monotherapy with ropinirole in patients with early PD significantly improves UPDRS motor scores by approximately 20% to 30% compared with baseline values.[38–40]

Rotigotine

Rotigotine is a nonergoline dopamine receptor agonist that is formulated in a transdermal patch delivery system designed for once-a-day application. It was voluntarily withdrawn from the U.S. market in 2008 because of problems with crystal formation in the patches; however, the patch was reformulated and re-approved by the Food and Drug Administration (FDA) in April 2012. The original and reformulated patches have demonstrated efficacy as monotherapy in early-stage PD,[41–44] whereas only the original formulation has demonstrated efficacy as adjunctive therapy to levodopa in patients with advanced stages of PD.[45],[46] It is, however, used in both situations.

A randomized, controlled trial conducted in Japanese patients with early-stage PD found that the mean improvement in UPDRS Part II and III sum scores was 8.4 in the rotigotine-treated group versus 4.1 in the placebo group ($P = 0.002$; 95% CI, –7.0 to –1.7).[47] The average dose of rotigotine was 12.8 mg/24 hours in this study which exceeds the highest recommended dose for early PD (6 mg/24 hours). Despite clear benefits in improving ADLs and motor function, there is insufficient evidence at this time to support that rotigotine prevents or delays motor fluctuations or dyskinesias.[48]

The transdermal delivery may have several advantages over traditional oral preparations including possible increase in adherence, ease of use in patients with swallowing difficulty, and a more continuous stimulation of dopamine receptors. In theory, these benefits may translate into improved efficacy. In randomized, controlled trials comparing rotigotine to ropinirole as monotherapy or pramipexole as adjunct therapy, rotigotine has been found to be noninferior when typical clinical doses are used.[44],[46]

Dosing

CASE 59-1, QUESTION 7: How are pramipexole and ropinirole dosed? What is the appropriate dose of pramipexole for L.M.?

Dopamine agonists should always be initiated at a low dosage and gradually titrated to the maximal effective dose, as tolerated. This approach minimizes adverse effects that may result in nonadherence or discontinuation of the drug. In clinical trials, the maximal effective doses are variable and correlate with disease severity and tolerability. Studies have found no difference in efficacy or safety measures between immediate and long-acting formulations of dopamine agonists.[49] One fixed-dose study of pramipexole in early PD showed that most patients responded maximally at a dosage of 0.5 mg 3 times daily, although it has been shown to be effective and well tolerated in doses as high as 4.5 mg/day (divided).[34]

L.M. has normal renal function; therefore, immediate-release pramipexole should be started at an initial dosage of 0.125 mg 3 times daily for 5 to 7 days. His dosage may be increased weekly by 0.125 to 0.25 mg/dose as tolerated and up to the maximal effective dose, not to exceed the maximum dose of 4.5 mg/day.[34] Patients with a creatinine clearance of less than 50 mL/minute should be dosed less frequently than those with normal renal function.[34] Patients with a creatinine clearance of 30 to 50 mL/minute should receive a starting dose of 0.125 mg twice daily up to a maximal dose of 0.75 mg 3 times daily; patients with a creatinine clearance of 15 to 30 mL/minute should receive a starting dose of 0.125 mg daily up to a maximal dose of 1.5 mg daily. Pramipexole has not been studied in patients with a creatinine clearance of less than 15 mL/minute or those receiving hemodialysis. A once-daily extended-release formulation of pramipexole is also available; patients can be switched overnight from immediate-release pramipexole at the same daily dose. The use of the extended-release formulation is not recommended for patients with a creatinine clearance less than 30 mL/minute or for those receiving hemodialysis.

Ropinirole should be initiated at a dosage of 0.25 mg 3 times daily with gradual titration to clinical response in weekly increments of 0.25 mg/dose over the course of 4 to 6 weeks, not to exceed 24 mg/day.[37] Patients wishing to take the drug less frequently can be switched directly to an extended-release once-daily formulation, selecting the dose that most closely matches the total daily dose of the immediate-release formulation. No dose adjustments for ropinirole are necessary in patients with renal dysfunction and can be used in doses up to 18 mg/day in patients on hemodialysis

Transdermal rotigotine is available in several patch strengths (Table 59-2). For patients with early-stage PD, it is recommended to start rotigotine at 2 mg/24 hours with dose increases of 2 mg/24 hours no sooner than weekly based on clinical response and tolerability.[50] The maximum recommended dose in early PD is 6 mg/24 hours whereas 8 mg/24 hours is recommended in advanced PD. Clinical trials have often used doses up to 16 mg/24 hours.[46],[51] The time to reach steady state plasma concentrations of rotigotine is approximately 2 to 3 days after initial patch application.[50] A multinational, open-label study demonstrated that patients with advanced PD taking pramipexole <2 mg/day or ropinirole <9 mg/day can be safely switched directly to rotigotine with no cross-titration.[52] Rotigotine is metabolized via conjugation and N-dealkylation, and the inactive conjugates are excreted in the urine. No adjustments are required for patients with hepatic or renal insufficiency.

Adverse Effects

CASE 59-1, QUESTION 8: What are the adverse effects of pramipexole and ropinirole? How can these be managed?

Because pramipexole, ropinirole, and rotigotine are all approved for use as monotherapy in early-stage disease and as adjunctive therapy in advanced-stage disease, the adverse events of these agents have been evaluated as a function of disease stage. In studies of patients with early-stage disease, the most common side effects were nausea (28%–47%), application site reactions (39%, rotigotine only), dizziness (25%–40%), somnolence (22%–40%), insomnia (17%–19%), constipation (14%), asthenia (14%), hallucinations (9%), and leg edema (5%).[21],[34–37,38–40,51] Administration with food may help to relieve nausea and/or vomiting. With continued use, many patients exhibit tolerance to the gastrointestinal side effects. CNS side effects were the most common reason for discontinuation of these agents with older patients particularly susceptible to hallucinations and other CNS side effects. The incidence of orthostatic hypotension was relatively low (1%–9%) and may in part reflect the exclusion of patients with underlying cardiovascular disease in several of the studies.

In advanced-stage disease, the most common adverse events of dopamine agonists were orthostatic hypotension (10%–54%), dyskinesias (26%–47%), application site reactions (46%, rotigotine only, dose related), nausea (25%), insomnia (27%), hallucinations (11%–17%), somnolence (11%), and confusion (10%).[34],[37],[50],[53] The most common reasons for discontinuing these agents are mental disturbances (e.g., nightmares, confusion, hallucinations, insomnia) and orthostatic hypotension. Dyskinesias that are experienced when dopamine agonists are used in combination with levodopa in advanced-stage disease may require lowering the dose of levodopa or, in some cases, the dopamine agonist.

Sudden, excessive daytime somnolence, including while driving, has been reported with dopamine agonists and has resulted in accidents.[34],[37],[50],[54] Affected patients did not always report warning signs before falling asleep and believed they were alert immediately before the event. Labeling for these drugs includes a warning that patients should be alerted to the possibility of falling asleep while engaged in daily activities. Patients should be advised to refrain from driving or other potentially dangerous activities until they have gained sufficient experience with the dopamine agonist to determine whether it will hinder their mental and motor performance. Caution should be advised when patients are taking other sedating medications or alcohol in combination with dopamine agonists. If excessive daytime somnolence does occur, patients should be advised to contact their healthcare practitioner.

Dopamine agonist therapy in patients with PD is associated with 2- to 3.5-fold increased odds of developing an impulse control disorder.[55] The frequency appears similar for both pramipexole and ropinirole whereas it is less clear with rotigotine. In one study, a prevalence of 6.1% was noted for pathologic gambling in patients with PD compared with 0.25% for age- and sex-matched controls.[56] These cases may represent variations of a behavioral syndrome termed dopamine dysregulation syndrome.[57] Other features of the syndrome have been reported, including punding (carrying out repetitive, purposeless motor acts), hypersexuality, walkabout (having the urge to walk great distances during on-times, often with no purpose or destination and abnormalities in time perception), compulsive buying, binge eating, drug hoarding, and social independence or isolation.[57] The syndrome appears to be more common among younger, male patients with early-onset PD, as well as those having novelty-seeking personality traits, depressive symptoms, and current use of alcohol or tobacco.[55],[58] Management of impulse control disorders can be challenging, because it often requires modification of dopaminergic therapies, which must be carefully balanced with the accompanying risk of worsening motor function. Underlying depression, if present, should be treated and may improve impulse control. Nonpharmacologic measures (such as limiting access to money or the Internet) may be helpful; in some cases, antipsychotic drugs may be considered, but must also be used carefully to avoid precipitating motor disability.[59]

Although L.M. is younger than 65 years of age, he may be at increased risk for visual hallucinations and cognitive problems from dopamine agonist therapy. He should be monitored closely for occurrence or exacerbation of these side effects. He should also be evaluated for lightheadedness before initiation of pramipexole and counseled to report dizziness or unsteadiness, because this may lead to falls. He should be reassured that if these effects are caused by pramipexole, they should subside with time and that he should not drive or operate complex machinery until he can assess the effect of the drug on his mental status. L.M. should be counseled about the possibility of excessive, and potentially unpredictable, daytime somnolence because pramipexole is introduced. L.M. does not appear to have a problem with excessive alcohol use; however, he and his family should be educated about his increased risk for impulse control disorders and advised to report any new, unusual, or uncharacteristic behaviors or increased use of alcohol.

MONOAMINE OXIDASE-B INHIBITORS

The monoamine oxidase-B inhibitors are irreversible inhibitors of MAO-B, a major enzymatic pathway responsible for the metabolism of dopamine in the brain, and inhibition increases the amount of striatal dopamine.[60] The discovery that ingestion of MPTP causes rapid and irreversible parkinsonism led to the finding that the neurotoxicity associated with MPTP is not directly caused by MPTP itself, but rather the oxidized product, L-methyl-4-phenylpyridinium (MPP).[7] The conversion to MPP is a two-step process mediated in part by MAO-B. Inhibition of MAO-B can inhibit the oxidative conversion of dopamine to potentially reactive peroxides. This finding has led investigators to study whether inhibition of this enzyme is neuroprotective.

Selegiline

In animals, pretreatment with selegiline (also referred to as deprenyl) protects against neuronal damage after the administration of MPTP.[29] The Deprenyl and Tocopherol Antioxidative Therapy of Parkinsonism (DATATOP) study was designed to test the hypothesis that the combined use of selegiline and an antioxidant (α-tocopherol) early in the course of the disease may slow disease progression.[61] The primary outcome was the length of time that patients could be sustained without levodopa therapy (an indication of disease progression). Early treatment with selegiline 10 mg/day delayed the need to start levodopa therapy by approximately 9 months compared with patients given placebo; however, long-term observation showed that the benefits of selegiline were not sustained and diminished with time. In an extension of the study, patients originally assigned to selegiline tended to reach the endpoint of disability after 1 year of observation even more quickly than did those not assigned to receive selegiline.[62] Initial selegiline treatment did not alter the development of levodopa adverse effects such as dyskinesias and wearing-off and on–off phenomena.

Although selegiline did not prove to be neuroprotective, the finding that MAO-B inhibitors can delay the need for dopaminergic therapy by at least several months is clinically relevant and is supported by several randomized, controlled trials.[63],[64] Aside from the DATATOP trial, studies of selegiline are limited by relatively small sample sizes. As a result, a large meta-analysis of MAO-B inhibitors in early PD was conducted.[30] When analyzed for selegiline, the levodopa dose necessary to control symptoms was 67 mg (14–119 mg; P = 0.01) lower in the selegiline arm. This analysis found that the total, motor, and ADL scores of the UPDRS were significantly improved in the selegiline arm at 3 months. A subsequent Cochrane Review found that the selegiline-treated arms scored 3.79 points better (95% CI: 2.21, 5.3) when looking at the weighted mean difference in motor UPDRS score.[29] Although oral selegiline continues to be FDA-approved only as adjunct treatment to carbidopa/levodopa, the evidence suggests efficacy in monotherapy, and it is used as monotherapy in practice.

Rasagiline

Rasagiline is a second-generation, irreversible selective inhibitor of MAO-B that is FDA-approved as both monotherapy and adjunct therapy in PD. Rasagiline is otherwise differentiated from selegiline primarily in that it is a more potent inhibitor of MAO-B and does not carry the same potential for adverse effects resulting from metabolites.[65] Like selegiline, rasagiline has also been found to protect from MPTP-induced parkinsonism in animal models.[29]

Rasagiline was studied as monotherapy in early PD in a randomized, double-blind, placebo-controlled trial comparing rasagiline 1 or 2 mg daily with placebo (n = 404).[66] After 6 months of therapy, the mean adjusted change in UPDRS scores compared with placebo was improved in both the 1- and 2-mg groups (P<0.001).[66] These changes are quantitatively similar to those

---

observed with levodopa therapy. This study used a delayed-start design, wherein at the end of the initial 6 months of treatment, patients who received placebo were then switched over to receive active treatment with rasagiline, and the rasagiline-treated patients continued on therapy. After an additional 6 months of study, it was found that patients receiving rasagiline for all 12 months had less functional decline than patients in whom rasagiline was delayed.[67] The mean adjusted difference in total UPDRS scores at 12 months for patients receiving rasagiline 2 mg/day for all 12 months was –2.29 compared with the delayed-start rasagiline 2-mg group (P = 0.01). As a result, rasagiline was FDA-approved for use as monotherapy in early PD. These encouraging findings also suggested that neuroprotection might be afforded by rasagiline and prompted a larger, more definitive study.

The Attenuation of Disease Progression with Azilect Given Once-daily (ADIAGO) study was also a randomized, placebo-controlled trial using the delayed-start methodology, but with a much larger sample size (n = 1,176).[68] Patients were randomly assigned to receive rasagiline or placebo for 36 weeks, at which time rasagiline-treated subjects continued therapy, and the placebo group was switched to rasagiline; all patients were then followed for an additional 36 weeks. To prove disease modification attributable to rasagiline with either dose, the early-start treatment group had to meet each of three hierarchic endpoints, based on magnitude and rate of change of UPDRS scores during different periods of the study. At the end of the study, rasagiline failed to meet all of the prespecified endpoints and the authors were unable to confirm any disease-modifying effects.[68]

No direct comparisons of rasagiline and selegiline are available. Existing data were compared in an industry-sponsored, indirect meta-analysis, which found a significant advantage for rasagiline monotherapy on UPDRS scores.[69] Additionally, risk for discontinuation and adverse events favored rasagiline. Rasagiline is primarily metabolized via cytochrome P450 (CYP) 1A2 and N-dealkylation, whereas selegiline is metabolized via CYP2B6, CYP2C9, and CYP3A4/5 to amphetamine-like metabolites (L-methamphetamine and L-amphetamine). As a result of their MAO-B inhibition, similar precautions regarding drug interactions exist; caution should be taken when using MAO-B inhibitors with proserotonergic agents such as antidepressants, triptans, and linezolid due to the risk of serotonin syndrome. Although tyramine-challenge studies have not demonstrated any clinically significant reactions with these MAO-B inhibitors, the product labeling still contains a warning that patients should be advised to restrict tyramine intake.[70],[71]

Dosing

Selegiline is available in a 5-mg capsule or tablet and as a 1.25-mg orally disintegrating tablet. It is also available in a transdermal patch, but this formulation is not approved for use in PD (approved for treatment of major depressive disorder). The bioavailability of conventional selegiline is low, and it undergoes extensive hepatic first-pass metabolism into amphetamine-based metabolites, which may contribute to neurologic side effects.[60] The usual dosage of conventional selegiline is 10 mg/day administered as 5 mg in the morning and early afternoon. It is not given in the evening because excess stimulation from metabolites (L-methamphetamine and L-amphetamine) can cause insomnia and other psychiatric side effects.[72] The orally disintegrating tablet formulation dissolves in the mouth in contact with saliva and undergoes pregastric absorption. This formulation minimizes the effect of first-pass metabolism in comparison with conventional selegiline, resulting in higher plasma concentrations and reductions in the amphetamine-based metabolites.[60] Selegiline should be used with caution in patients with severe hepatic impairment or with creatinine clearance less than 30 mL/minute.

Rasagiline is available in 0.5- and 1-mg tablets. When used as monotherapy, it is initiated at 1 mg daily. When combined with levodopa, the initial dose is lowered to 0.5 mg daily and can be increased to 1 mg daily based on response. In patients with mild hepatic impairment, the dose should be reduced to 0.5 mg daily, but use should be avoided in those with moderate-to-severe hepatic impairment. Additionally, because rasagiline lacks the amphetamine-like metabolites of selegiline, it also lacks the time-specific dosing constraints.

Adverse Effects

The most common adverse effects of both agents include nausea (6%–20%), dizziness (11%–14%), headache (4%–14%), and dry mouth (4%–6%).[60],[70],[72] CNS effects such as hallucinations, vivid dreams, and confusion also occur but at a lower rate as compared with dopamine agonists. Although the oral disintegrating tablet reduces the amphetamine-based metabolites, there are higher rates of reported side effects, likely as a result of the higher plasma concentration of selegiline.[60] A large meta-analysis of MAO-B inhibitors in early PD found a higher incidence of reported side effects among the MAO-B inhibitor (all but one study used selegiline) versus non-MAO-B inhibitor groups (OR: 1.36, 1.02–1.8, P = 0.04).[30] However, these agents are generally considered well tolerated.[70]

LEVODOPA

CASE 59-1, QUESTION 9: L.M. has responded well to pramipexole 1 mg 3 times daily for the past 18 months, with an increased ability to paint and carry out ADLs. During the past few weeks, however, he has noticed a gradual worsening in his symptoms and once again is having difficulty holding a paintbrush. He currently complains of feeling more "tied up," he has more difficulty getting out of a chair, and his posture is slightly more stooped. He also notes that he feels tired throughout much of the day. He remains able to carry out most of his ADLs without assistance. Should levodopa be considered for the treatment of his PD symptoms at this time?

Dopamine itself does not cross the blood–brain barrier. Levodopa, a dopamine precursor with no known pharmacologic action of its own, crosses the blood–brain barrier, where it is converted by the enzyme aromatic amino acid (dopa) decarboxylase to dopamine. Levodopa has been a mainstay of PD treatment since the 1960s. Nearly all patients will eventually require treatment with the drug, regardless of their initial therapy.

Because significant amounts of levodopa are peripherally (extracerebrally) metabolized to dopamine by dopa decarboxylase, extremely high doses are necessary if administered alone. For this reason, levodopa is always coadministered with a dopa decarboxylase inhibitor. This allows the dose of levodopa to be decreased by 75%.[73] By combining levodopa with a dopa decarboxylase inhibitor that does not penetrate the blood–brain barrier, a decrease in the peripheral conversion of levodopa to dopamine can be achieved, whereas the desired conversion within the striatum remains unaffected. This combination also shortens the time needed to achieve optimal effects by several weeks, because the dopa decarboxylase inhibitor substantially decreases dose-limiting levodopa-induced nausea and vomiting. The two peripheral decarboxylase inhibitors in clinical use are benserazide (unavailable in the US) and carbidopa. A fixed combination of carbidopa and levodopa is available in ratios of 1:4 (carbidopa/levodopa 25/100) and 1:10

(carbidopa/levodopa 10/100 and 25/250). Carbidopa/levodopa is also available as an immediate-release, orally disintegrating tablet and extended-release capsule, both of which may be used in early PD. In addition, controlled-release, extended-release, and intestinal gel

formulations are available and are discussed for management of motor complications.

The optimal time to initiate levodopa therapy must be individualized because chronic levodopa use is associated with the development of motor complications and dyskinesias. These observations led to the understanding that chronic levodopa therapy may actually accelerate the neurodegenerative process through formation of free radicals generated by dopamine metabolism.[74] The Earlier versus Later Levodopa Therapy in Parkinson's Disease (ELLDOPA) study was designed to determine whether long-term use of levodopa accelerates neurodegeneration and paradoxically worsens PD.[74] After 42 weeks, the severity of symptoms as measured by changes in the total UPDRS score increased more in the placebo group than in all of the groups receiving levodopa. This validated that levodopa use does not result in accelerated progression of the disease based on clinical evaluations. In untreated individuals, there is little reason to start levodopa until the patient reports worsening of function (socially, vocationally, or otherwise). The need for levodopa therapy may be delayed by initiating therapy first with a dopamine agonist or MAO-B inhibitor. This approach is particularly advantageous in younger patients who will likely live many years with PD and have a high lifetime risk for developing motor complications. In the case of L.M., he is now experiencing bothersome symptoms despite near-maximal dopamine agonist therapy, and it has progressed sufficiently to threaten his job performance. Although the dose of pramipexole could be increased, he may experience more daytime somnolence; thus, levodopa should be added to his regimen.

Dosing

CASE 59-1, QUESTION 10: The decision is made to begin L.M. on carbidopa/levodopa. How should it be dosed?

About 70 to 100 mg/day of carbidopa is necessary to saturate peripheral dopa decarboxylase.[73] It is usually unnecessary and more costly to administer carbidopa in higher amounts. Therapy should be initiated with immediate-release carbidopa/levodopa 25 mg/100 mg 3 times a day. The immediate-release formulation is preferred because it allows for much easier dose adjustment. In the case of L.M., the dose can then be increased by 100 mg of levodopa every day or every other day up to eight tablets (800 mg) or to the maximal effective dose, to individual requirements, or as tolerated.

Troublesome peak-dose dyskinesias may occur as a result of high levels of dopaminergic drug activity. If these occur, the dose or frequency may be adjusted, while giving consideration to balancing the most useful dose (e.g., maximizing the patient's on-time) with that which does not produce unacceptable side effects (e.g., troublesome dyskinesias). Because L.M. is currently being treated with a dopamine agonist, he must be monitored closely for the development of motor complications with the addition of levodopa.

Most patients with early PD will begin therapy on levodopa 300 mg/day and will demonstrate response before reaching 1,000 mg/day.[11,73] When levodopa doses exceed 750 mg/day, patients such as L.M. can be switched from the 1:4 ratio of carbidopa/levodopa to the 1:10 ratio to prevent providing excessive amounts of decarboxylase inhibitor. For example, if L.M. needed 800 mg/day of levodopa, two carbidopa/levodopa 10/100 tablets 4 times daily could be administered. If L.M. had not been initially treated with a dopamine agonist, some clinicians would consider adding a dopamine agonist after the daily levodopa dose has been increased to more than 600 mg because dopamine agonists directly stimulate dopamine receptors, have longer half-lives, and result in a lower incidence of dyskinesias, thus providing a smoother dopaminergic response.

Clinical response to levodopa therapy may be altered by modifying dietary amino acid ingestion.[73] Levodopa is actively transported across the blood–brain barrier by a large neutral amino acid transport system. This transport system also facilitates the blood-to-brain transport of amino acids such as L-leucine, L-isoleucine, L-valine, and L-phenylalanine. Levodopa and these neutral amino acids compete for transport mechanisms, and high plasma concentrations of these amino acids can decrease brain concentrations of levodopa.[75] Patients should be instructed to take immediate-release carbidopa/levodopa 30 minutes before or 60 minutes after meals for optimal efficacy. If nausea develops and administration with food is considered, a low-protein meal should be encouraged.

Adverse Effects

CASE 59-1, QUESTION 11: Since initiating carbidopa/levodopa, L.M. reports feeling restless and agitated at times. To what extent is levodopa contributing to these problems? How should they be managed?

Although levodopa is the most effective agent for PD, it is associated with many undesirable side effects, such as nausea, vomiting, and anorexia (50% of patients); postural hypotension (30% of patients); and cardiac arrhythmias (10% of patients).[11] In addition, mental disturbances are encountered in 15% of patients, and abnormal involuntary movements (dyskinesias) can be seen in up to 55% of patients during the first 6 months of levodopa treatment.[76]

Although more commonly encountered with dopamine agonists, psychiatric side effects are also associated with levodopa therapy and include confusion, depression, psychosis, hypomania, and vivid dreams.[73] Those with underlying or preexisting psychiatric disorders and those receiving high doses of levodopa for prolonged periods are at greatest risk.[77] Concurrent anticholinergics or amantadine therapy can exacerbate these symptoms. Advancement of the PD itself correlates with cognitive decline and greater frequency of CNS findings, possibly mediated through an underlying Lewy body pathology.[17] In some situations, it may be difficult to separate the respective drug from disease effects.

Some patients receiving levodopa experience psychomotor excitation (e.g., overactivity, restlessness, agitation). Similarly, hypomania has been reported in up to 8% of patients and is characterized by grandiose thinking, flight of ideas, tangential thinking, and poor social judgment. Normal sexual activity often is restored with improved motor function; however, hypersexuality and libido are increased in about 1% of levodopa-treated patients.[77]

In general, most of the mental disturbances are dose-related and can be lessened by reducing the dose of the dopaminergic agent. In patients such as L.M. who are concurrently receiving levodopa and a dopamine agonist, the dose reduction should be attempted first with the dopamine agonist. If symptoms do not improve, a reduction in the dose of levodopa may also be warranted. These dose reductions may, however, be impractical for L.M. because a return of parkinsonian symptoms is likely, and the benefits of levodopa therapy may outweigh the risk for mental disturbances.

ANTICHOLINERGICS

CASE 59-1, QUESTION 12: What role do anticholinergic drugs play in the treatment of PD? Should L.M. receive an anticholinergic agent?

Anticholinergic drugs have been used to treat PD since the mid-1800s, when it was discovered that symptoms were reduced by the belladonna derivative hyoscine (scopolamine).[17] Currently,

---

they are used to specifically target tremor. Although tremor may improve with dopaminergic drugs via the restoration of balance between dopamine and acetylcholine, resolution of tremor may be incomplete. Anticholinergic drugs such as benztropine and trihexyphenidyl work by blocking the excitatory neurotransmitter acetylcholine in the striatum, which minimizes the effect of the relative increase in cholinergic sensitivity. Until the late 1960s, when amantadine and levodopa were introduced, anticholinergics were a mainstay of treatment; however, because of their undesirable side effect profile and poor efficacy relative to levodopa in treating bradykinesia and rigidity, anticholinergic agents are no longer used as first-line agents. These drugs produce both peripherally and centrally mediated adverse effects. Peripheral effects, such as dry mouth, blurred vision, constipation, and urinary retention, are common and bothersome.[20] Anticholinergic agents can increase intraocular pressure and should be avoided in patients with angle-closure glaucoma. CNS effects can include confusion, impairment of recent memory, hallucinations, and delusions.[17],[20] Patients with PD are often more susceptible to these central effects because of advanced age, intercurrent illnesses, and impaired cognition.[20] Anticholinergics are usually reserved for the treatment of resting tremor early in the disease, particularly in younger patients with preserved cognitive function. Given his history and clinical presentation and based on the absence of tremor, L.M. would not be an appropriate candidate for an anticholinergic drug.

Treatment through the Progression of Parkinson’s Disease

LEVODOPA AND ADJUNCTIVE THERAPY

The chronic, progressive nature of PD predicts that patients will develop worsening of motor control through the later stages of the disease; thus, enhanced motor control through the use of levodopa, in conjunction with symptomatic adjunctive agents, will be necessary. Agent selection is guided by efficacy for motor symptom control, adverse effects, and motor complication risk. Agents indicated by the AAN,[16] EFNS/MDS-ES,[18] and NICE[17] guidelines for symptomatic adjunct therapy and management of motor complications in late PD are outlined in Figure 59-3.

MOTOR COMPLICATIONS

CASE 59-1, QUESTION 13: L.M. had a dramatic improvement in all of his parkinsonian symptoms with the initiation of levodopa therapy after being maintained on carbidopa/levodopa 25 mg/250 mg 4 times a day.

After 6 months of treatment, he began to experience dyskinesias occurring 1 to 2 hours after a dose. They manifested as facial grimacing, lip smacking, tongue protrusion, and rocking of the trunk. Decreasing his pramipexole dose to 0.5 mg 3 times daily and gradually decreasing his dosage of carbidopa/levodopa to 25 mg/250 mg 3 times daily lessened the symptoms. After 3 years of levodopa therapy, more serious problems have begun to emerge. In the mornings, L.M. often experiences immobility. Nearly every day, he has periods (lasting for a few minutes) in which he cannot move, followed by a sudden switch to a fluid-like state, often associated with dyskinetic activity. He continues to take carbidopa/levodopa 3 times daily, but gains symptomatic relief for only 3 to 4 hours after a dose. Also, the response to a given dose varies and is often less in the afternoon. At times, he becomes “frozen,” particularly when he needs to board an elevator or is required to move quickly. What are possible explanations for these alterations in clinical response?

Though variable, the initial levodopa response period may last up to 5 years. After this initial period of stability, 50% to 90% of patients receiving levodopa for 5 or more years will eventually experience motor complications.[78] Motor complications may present as periods of either too much (dyskinetic) dopaminergic activity, too little (akinetic) dopaminergic activity, or in combination.

In evaluating these motor fluctuations, it is important to ascertain which effects are attributable to the disease and which are attributable to the drug. For example, levodopa-induced peak-dose dyskinesias often appear concurrently with the development of motor fluctuations.[78],[79] Peak-dose choreiform dyskinesias, brief, irregular and jerky movements, are the most common form of dyskinesias that occur with chronic levodopa (and sometimes dopamine agonist) therapy. These symptoms frequently subside at the end of the dosing interval because levodopa levels fall. Their severity is related to levodopa dose, disease duration and stage, and younger age at onset.[79] If peak-dose dyskinesias occur, the following strategies should be considered: The levodopa dose can be lowered but given more frequently; consideration can be given to switching patients to immediate-release tablets if taking modified-release formulations of carbidopa/levodopa (for ease in refining dose adjustments); agents that prolong the half-life of levodopa but do not provide stable levodopa plasma concentrations (e.g., COMT inhibitor, MAO-B inhibitor) can be added; or an antidyskinetic agent such as amantadine can be used. Variations in the rate and extent of levodopa absorption, dietary substrates (e.g., large neutral amino acids) that compete with cerebral transport mechanisms, levodopa drug–drug interactions (Table 59-4), and competition for receptor binding by levodopa metabolites can further explain the variable responses observed to levodopa.

Two of the more common motor complications are the wearing-off effect and the on–off effect. The wearing-off effect is most predictable, occurring in the latter part of the dosing interval after a period of relief. Because levodopa is a short-acting agent with an elimination half-life of about 1.5 hours, much of the effect from the evening dose will dissipate by morning.[73],[78] For this reason, it is not surprising that L.M. is experiencing a period of immobility on arising. This is alleviated in most patients shortly after taking the morning dose. Wearing off can be improved by various means such as shortening the dosing interval or with the addition of adjunctive therapy (if not already present) with a dopamine agonist, MAO-B inhibitor or levodopa extender such as a COMT inhibitor. The on–off effect is described as random fluctuations from mobility (often associated with dyskinesias) to the parkinsonian state, which appear suddenly as if a switch has been turned on or off. These fluctuations can last from minutes to hours and increase in frequency and intensity with time. Despite accompanying dyskinesias, most patients prefer to be in an on rather than an off (or akinetic) state; however, for some patients, dyskinesias can be more disabling than parkinsonism.

Early in the course of disease, it is usually possible to control parkinsonian symptoms without inducing dyskinesias via medication adjustments; however, because the disease advances and the therapeutic window narrows, cycling between on periods complicated by dyskinesia and off periods with resulting immobility is common.[78],[79] Eventually, despite adjustments in levodopa dose, many patients with advanced PD experience either mobility with severe dyskinesias or complete immobility. In most patients, this effect has no clear relationship to the timing of the dose or levodopa serum levels.[78]

The pathophysiologic basis for motor complications and dyskinesias is not entirely clear, but incomplete delivery of dopamine to central receptors is likely responsible.[78] Because the disease progresses and dopamine terminals are lost, the capacity to store dopamine presynaptically is diminished, impairing the ability to maintain relatively constant striatal dopamine concentrations.[78] As a consequence, dopamine receptors are subject to intermittent, pulsatile stimulation, rather than a more physiologic tonic stimulation. Overactivity of excitatory pathways mediated by neurotransmitters such as glutamate may also be involved.[78]

CASE 59-1, QUESTION 14: What options are available to reduce the motor fluctuations experienced by L.M.?

MODIFIED-RELEASE CARBIDOPA/LEVODOPA FORMULATIONS

A more sustained delivery of levodopa than that achieved with routine oral dosing may theoretically reduce motor complications, by more effectively replicating normal physiology. Three products designed to prolong carbidopa/levodopa delivery include a controlled-release tablet, an extended-release capsule, and an enteral suspension administered as a gastrointestinal infusion. The use of the enteral suspension for gastrointestinal infusion has shown reductions in off-time of 1.91 hours ($P = 0.0018$) and an increase in on-time of 1.86 hours ($P = 0.0059$) in a 12-week study of patients with severe motor fluctuations and hyper/dyskinesias.[80] As a result of its pump administration via a permanent duodenal/upper jejunal tube, this method is typically reserved as last-line therapy for use in specialized centers.

Controlled-Release Carbidopa/Levodopa

A controlled-release (CR) tablet formulation of carbidopa/levodopa is available, containing 25-mg carbidopa and 100-mg levodopa or 50-mg carbidopa and 200 mg levodopa in an erodible polymer matrix that retards gastric dissolution. Although off-time should theoretically be reduced by the slower rate of plasma levodopa decline, clinical study has generally not found a sustained difference in off-time, or a reduction in dyskinesias, with the CR preparation compared with the immediate-release preparation.[17],[18] As a result, switching to CR carbidopa/levodopa as a primary strategy to reduce off-time or lessen dyskinesias is not recommended.[17]

A likely reason for the lack of superior effect with CR carbidopa/levodopa as compared with the immediate-release formulation is its variable absorption.

Controlled-release carbidopa/levodopa is about 30% less bioavailable than the immediate-release formulation. Patients converted from standard carbidopa/levodopa to the CR formulation should receive a dose that will provide 10% more levodopa, and then the dose should be titrated upward to clinical reponse.[81] Interestingly, administration with food enhances levodopa peak by 25%. Given that there is no obvious advantage to CR carbidopa/levodopa, L.M. should not be switched to this formulation.

Extended-Release Carbidopa/Levodopa

The extended-release (ER) capsule formulation of carbidopa/levodopa contains a combination of both immediate- and extended-release beads designed to circumvent the pharmacokinetic concerns seen with the CR tablet formulation. Although both formulations persist for up to 6 hours, the ER capsule provides a faster time to symptom relief, with a peak that is comparable to the immediate-release formulation (1 hour vs. up to 2 hours for CR).[82] Similar to CR, the ER formulation reduces levodopa bioavailability by approximately 50%.[83] As such, the manufacturer provides specific dose conversions from immediate-release preparations. Converse to the CR preparation, high-fat and high-calorie food reduces levodopa peak and may delay absorption by 2 to 3 hours, and it is recommended that the first dose of the day be given 1 to 2 hours prior to eating. In patients with difficulty swallowing, these capsules may be opened and sprinkled on applesauce, which is an additional advantage to the CR formulation.

The ability of the ER formulation to reduce off-time was evaluated in a placebo-controlled study randomizing 393 patients to immediate or ER formulations over 22 weeks.[84] After being titrated to a stable dose during weeks 1 to 9, patients were followed for an additional 13 weeks. Compared to baseline evaluations, extended-release patients had a reduction in off-time by approximately 1 hour/day ($P<0.0001$) when compared to the IR formulation. This effect was accompanied by an increase in on-time without troubling dyskinesia of approximately 1 hour ($P = 0.0002$). Notably, of patients converted per manufacturer direction, 60% of patients required a further dosage increase and 13% required a dosage decrease.[84]

Table 59-4

Levodopa Drug Interactions

Drug	Interaction	Mechanism	Comments
Anticholinergics	↓ Levodopa effect	↓ Gastric emptying, thus ↑ degradation of levodopa in gut, and	Watch for ↓ levodopa effect when anticholinergics cause ↓ GI motility. When anticholinergic therapy is discontinued in a

		↓ amount absorbed	patient on levodopa, watch for signs of levodopa toxicity. Theoretic interaction with minor clinical significance
Ferrous sulfate	↓ Levodopa oral absorption by 50%	Formation of chelation complex	Avoid concomitant administration or separate administration by at least 2 hours
Food	↓ Levodopa effect	Large, neutral amino acids compete with levodopa for intestinal absorption	Although levodopa is usually taken with meals to slow absorption and ↓ central emetic effect, high-protein diets should be avoided
MAOI (e.g., phenelzine, tranylcypromine)	Hypertensive crisis	Peripheral dopamine and norepinephrine	Avoid combination use; monoamine oxidase type B (MAO-B) inhibitors such as selegiline can be used, but the dose of levodopa should be reduced after 2–3 days of therapy; carbidopa might minimize hypertensive reaction to levodopa in patients receiving an MAOI.
Methyldopa	↑ or ↓ levodopa effect	Acts as central and peripheral decarboxylase inhibitor	Observe for response; may need to switch to another antihypertensive.
Metoclopramide	↓ Levodopa effect	Central dopamine blockade	Avoid combination use
Neuroleptics (e.g., butyrophenones, phenothiazines)	↓ Levodopa effect	Central blockade of dopamine neurotransmission	Avoid combination use; important interaction
Phenytoin	↓ Levodopa effect	Mechanism unknown	Avoid combination use
Pyridoxine (vitamin B6)	↓ Levodopa effect	Peripheral decarboxylation of levodopa	Not observed when levodopa given with carbidopa; avoid levodopa monotherapy with vitamin B6 supplementation
Tricyclic antidepressants	↓ Levodopa effect	Levodopa degradation in gut because of delayed emptying	Use with caution

GI, gastrointestinal; MAOI, monoamine oxidase inhibitor.

Based upon this evidence, the ER formulation may improve off-time for L.M., but is unlikely to impact his dyskinesias. Therefore, it may not be appropriate to switch therapy. Taking his immediate-release carbidopa/levodopa more frequently while avoiding substantial increases in the total daily dose, which could worsen his dyskinesias, may improve his condition. Taking his morning dose before arising from bed may help with his early-morning problems. If the symptoms that L.M. is experiencing are not improved with these changes, a number of adjunctive agents such as dopamine agonists, apomorphine rescue, amantadine, COMT inhibitors, and MAO-B inhibitors can be considered.

DOPAMINE AGONISTS

The effectiveness of pramipexole added to levodopa therapy in advanced PD was evaluated in a multicenter, placebo-controlled study of 360 patients with a mean disease duration of 9 years.[85] Pramipexole was titrated gradually to the maximal effective dose as tolerated. At the end of a 6-month maintenance period, patients treated with pramipexole had a 22% improvement in their ADLs (P<0.0001) and a 25% improvement in their motor scores (P<0.01) compared with baseline values. Patients treated with pramipexole also had a 31% improvement in the mean off-time, compared with a 7% improvement in the placebo-treated group (P<0.0006). Dyskinesias and hallucinations were more common in pramipexole-treated patients and necessitated levodopa dose reduction in 76% of patients compared with 54% in the placebo group. The total daily levodopa dose was decreased by 27% in those treated with pramipexole compared with 5% in the placebo group.

Ropinirole has been found to improve motor scores when added to levodopa therapy in patients with advanced-stage disease.[53] In a multicenter, double-blind, randomized parallel-group study, patients treated with ropinirole achieved a greater reduction in percent of time spent off during waking hours when compared to placebo (11.7% vs. 5.1%), which was a difference of 0.4 hours. A greater amount of ropinirole-treated patients achieved a significant 20% reduction in time spent off (35% vs. 13%, P = 0.003). In those treated with levodopa, the levodopa dose was decreased by an average of 19%.

Long-acting dopamine agonist formulations, including ER ropinirole and rotigotine, have also shown reductions in off-time. In a study of 208 PD patients not optimally controlled with levodopa after up to 3 years of therapy with less than 600 mg/day of levodopa, a prolonged-release, once-daily formulation of ropinirole was found to improve motor scores in a similar fashion to increase the levodopa dose; however, only 3% of ropinirole-treated subjects experienced dyskinesias compared with 17% of levodopa-treated patients (P<0.001).[86] In moderate-to-advanced PD, treatment benefits were observed within 2 weeks of initiation.[87] Extended-release ropinirole has been found to reduce off-time more than the immediate-release preparation in advanced PD. A randomized, double-blind trial of 343 patients over 24 weeks found that compared to the immediate-release formulation, significantly more patients given the ER formulation maintained at least a 20% reduction in off-time (adjusted OR: 1.82, 1.16–2.86, P = 0.009).[88] These results are confounded by the relatively higher doses of ER ropinirole and greater reductions in levodopa achieved by the ER formulation. Rotigotine has also been evaluated for reduction in off-time in advanced PD patients and has been shown to significantly reduce off-time by approximately 2.5 hours, with benefits seen as early as the first week of therapy.[50]

Because L.M. has advanced disease and is experiencing motor fluctuations despite a treatment regimen that includes a dopamine agonist, further dose adjustments of the dopamine agonist may provide little additional benefit. Any adjustments must be made with consideration of worsening his dyskinesias and the possibility of exacerbating CNS adverse effects.

Apomorphine

Apomorphine is an injectable dopamine agonist that is approved as rescue therapy for treatment of hypomobility or off episodes in patients with PD. In a randomized, double-blind, parallel-group study of 29 patients, rescue treatment with apomorphine resulted in a 34% reduction in off-time, approximately 2 hours, compared with 0% in the placebo group ($P = 0.02$).[89] Mean UPDRS motor scores were reduced by 23.9 points (62%) in those treated with apomorphine, compared with 0.1 (1%) in those receiving placebo ($P<0.001$). Adverse events in the apomorphine group included yawning (40%), dyskinesias (35%), drowsiness or somnolence (35%), nausea or vomiting (30%), and dizziness (20%), although only yawning was statistically different from placebo (40% vs. 0%; $P = 0.03$).

Because nausea and vomiting frequently occur with apomorphine treatment, it should be administered with an antiemetic such as trimethobenzamide. The antiemetic should be started 3 days before initiating apomorphine and continued for the first 2 months of treatment.[89] Apomorphine should not be used with ondansetron and other serotonin antagonists used to treat nausea because the combination may cause severe hypotension. In addition, other antiemetics, such as prochlorperazine and metoclopramide, should not be given concurrently because these dopamine antagonists may decrease the effectiveness of apomorphine.

Doses of apomorphine range from 2 to 6 mg per subcutaneous injection. A 2-mg test dose is recommended while monitoring blood pressure. If tolerated, the recommendation is to start with a dose of 2 mg and increase the dose by 1 mg every few days if needed. Peak plasma levels are observed within 10 to 60 minutes after dosing, so the onset of therapeutic effect is rapid. The test dose and titration are time-consuming and must be done under physician supervision, and patients may require someone else to inject the drug once hypomobility has occurred. In severe cases, subcutaneous infusions have been used, but are limited to research settings and high-level clinical centers. For these reasons, apomorphine is not widely used. Given that L.M. is experiencing motor fluctuations almost daily, long-term frequent apomorphine use would not be a viable solution in his situation.

AMANTADINE

The antiviral agent, amantadine, was serendipitously found to improve PD symptoms when a patient given the drug for influenza experienced a remission in her parkinsonism.[90] Amantadine reduces all the symptoms of parkinsonian disability in about 50% of patients, usually within days after starting therapy; however, early trials indicated that amantadine efficacy might be limited by the development of tachyphylaxis within 1 to 3 months.[91] Although the trials suggested reductions in dyskinesias by up to 40%, previous evaluations of amantadine for the reduction of dyskinesias have been limited by methodological concerns.

The pathophysiologic basis for the efficacy of amantadine in PD is not entirely understood; it may augment dopamine release and possibly inhibit its reuptake.[92] Anticholinergic action has also been suggested. Excess glutamatergic activity has been implicated in the pathophysiology of dopaminergic dyskinesias; amantadine has been found to be an antagonist at N-methyl-D-aspartate (NMDA) receptors and to block glutamate transmission.[93] Amantadine has consistently shown approximately 50% reductions in dyskinesia severity and duration, without adversely impacting motor performance.[94–97] Two trials have evaluated long-term efficacy of amantadine in patients with levodopa-induced dyskinesia after treatment for 6 months to 1 year. These trials assessed for change in UPDRS motor examination and motor complication subscores with amantadine washout over 3 weeks to 3 months. Those discontinuing amantadine had deterioration in levodopa-induced dyskinesia compared to the continuing group within a median time of 7 days suggesting the possibility of continued benefit despite the tachyphylaxis suggested in earlier trials.[98],[99] Guidance suggests reserving consideration for amantadine use to those in whom dyskinesia is not adequately managed on other therapies.[17]

The decision to use amantadine in L.M. should be based on whether his dyskinesias are deemed more problematic than his duration of off-time. If so, amantadine should be started at 100 mg/day taken at breakfast; an additional 100-mg dose can be taken with lunch 5 to 7 days after initiation. The dose can be increased to a maximum of 300 mg/day; however, doses in excess of 200 mg/day are associated with increased adverse effects and should be used cautiously. Amantadine is renally excreted, and the dose should be reduced in patients with renal impairment.[100] If the dyskinesias that L.M. is experiencing are tolerable but the duration of off-time is more problematic, then selection of another agent such as a COMT inhibitor or MAO-B inhibitor may be more appropriate than the initiation of amantadine at this time.

Side effects of amantadine mainly involve the gastrointestinal (e.g., nausea, vomiting) and CNS (e.g., dizziness, confusion, insomnia, nightmares, and hallucinations). Patients receiving concomitant anticholinergic therapy may experience more prominent CNS side effects.[100] Livedo reticularis, a rose-colored mottling of the skin usually involving the lower extremities, can occur with amantadine as early as 2 weeks after initiating therapy. The consequences of livedo reticularis are entirely cosmetic, and discontinuation of therapy is unnecessary. Ankle edema may be seen in association with livedo reticularis. Elevation of the legs, diuretic therapy, and dosage reduction often alleviate the edema.

CATECHOL-O-METHYLTRANSFERASE INHIBITORS

COMT is an enzyme widely distributed throughout the body that is responsible for the biotransformation of many catechols and hydroxylated metabolites, including levodopa. When carbidopa, an inhibitor of aromatic AAD, is coadministered with levodopa, the peripheral conversion of levodopa to dopamine via this pathway is inhibited; as a consequence, the conversion of levodopa to 3-O-methyldopa (3-OMD) by COMT is amplified and becomes the major metabolic pathway for levodopa degradation. The metabolite 3-OMD lacks antiparkinsonian activity and may compete with levodopa for transport into the circulation and brain. By preventing its peripheral degradation, the therapeutic effect of levodopa can be extended via inhibition of COMT.

Entacapone and tolcapone are selective, reversible, and potent COMT inhibitors that increase the amount of levodopa available for transport across the blood–brain barrier (Figure 59-4) to prolong its therapeutic effect. Use of these agents is associated with increased on-time and a decrease in the daily levodopa dose.[101],[102] The pharmacologic and pharmacokinetic effects of entacapone and tolcapone are compared in Table 59-5.[101–103] Two uncontrolled trials and one controlled evaluation of patients with motor fluctuations newly placed on entacapone compared switching patients to tolcapone versus continuing the newly started entacapone. These trials alluded to the therapeutic benefits of tolcapone compared to entacapone; however, tolcapone is associated with cases of fatal, acute fulminant liver failure. This has led to stringent liver function monitoring requirements and limited clinical use. If initiated, liver function monitoring should be performed at baseline and every 2 to 4 weeks for the first 6 months, followed periodically thereafter as clinically necessary.[101] Because of the risks for hepatotoxicity associated with tolcapone, entacapone is the preferred COMT inhibitor and would be a good choice for L.M. if he desires an increase in his on-time.

Entacapone

CASE 59-1, QUESTION 15: Six months after adjusting the frequency of his carbidopa/levodopa dose and adding amantadine, L.M. reports that his dyskinesias are not too bothersome, but he is now having increased periods (lasting a few minutes) in which he cannot move. He is currently taking amantadine 100 mg twice daily, pramipexole 0.5 mg 3 times daily, and immediate-release carbidopa/levodopa 25 mg/250 mg 5 times a day, but "even on a good day" gains symptomatic relief for only about 2 to 3 hours after a dose. The decision is made to initiate entacapone therapy and gradually discontinue pramipexole as guided by symptoms or side effects. How effective is entacapone for reducing the symptoms of PD?

Early initiation of a COMT inhibitor at the same time that levodopa is first introduced has been proposed as a way of reducing the development of levodopa-induced motor complications[104]; theoretically, this strategy should provide more stable plasma levels of levodopa and lessen pulsatile stimulation of striatal dopamine receptors normally observed with intermittent levodopa dosing. This strategy was tested in the Stalevo Reduction in Dyskinesia Evaluation in Parkinson Disease (STRIDE-PD) study, a multicenter, double-blind study that randomly assigned 747 patients to initiate either carbidopa/levodopa or carbidopa/levodopa/entacapone 4 times daily.[104] Surprisingly, patients randomly assigned to receive carbidopa/levodopa/entacapone actually had a shorter time to onset of dyskinesia (hazard ratio: 1.29; $P = 0.04$) and increased dyskinesia frequency at week 134 (42% vs. 32%; $P = 0.02$). These findings may have been confounded by an increased use of dopaminergic therapy in the entacapone group. The findings of the STRIDE-PD study do not support the early administration of entacapone in combination with levodopa to reduce the occurrence of motor complications.

Table 59-5

Pharmacologic and Pharmacokinetic Properties of Catechol-O-Methyltransferase Inhibitors

	Tolcapone	**Entacapone**
Bioavailability	65%–68%	35%
T_{max} (hours)	1.7	1
Protein binding	99.9%	98%
Metabolism	Glucuronidation; CYP3A4, CYP2A6 methylated by COMT	Isomerization, glucuronidation
Half-life (hours)	2–3	Biphasic; 0.4–0.7, 2.4
Time to reverse COMT inhibition (hours)	16–24	8
Maximal COMT inhibition at 200-mg dose	>80%	65%
Increase in levodopa AUC	100%	35%
Increase in levodopa half-life	75%	85%
Dosing method	TID, spaced 6 hours apart	With every administration of levodopa

AUC, area under the curve; COMT, catechol-O-methyltransferase; CYP, cytochrome P-450; TID, three times daily.

The efficacy and safety of entacapone as an adjunct to levodopa therapy in the presence of motor complications was established in two pivotal multicenter, randomized, double-blind, placebo-controlled trials.[105],[106] Subjects for both studies had idiopathic PD with motor fluctuations, including wearing-off phenomena, despite maximal tolerated doses of levodopa. In both trials, patients were randomly assigned to receive either entacapone 200 mg or placebo (up to 10 doses/day) with each dose of carbidopa/levodopa.[105],[106] In both trials, significant improvements in off-time (approximately 1 hour), UPDRS scores (10% improvement), and levodopa doses (reductions of approximately 80–100 mg/day) were consistent.

Dosing

CASE 59-1, QUESTION 16: When should entacapone be initiated in L.M., and how should it be dosed?

Entacapone is approved for use as adjunctive therapy to levodopa for the treatment of PD in patients experiencing wearing-off or end-of-dose deterioration. It is given as one 200-mg tablet with each carbidopa/levodopa administration, up to eight tablets/day. It is available in a combination tablet with a 1:4 ratio of immediate-release carbidopa/levodopa that patients can be switched to once they are stabilized on individual formulations of carbidopa/levodopa and entacapone. If dyskinesias occur, it may be necessary to lower the levodopa dose by approximately 10% to 25%, particularly if the patient is receiving more than 800 mg/day of levodopa. Although pramipexole is being discontinued in L.M., he should still be monitored for dyskinesias, especially during the first few weeks of therapy, as it may also be necessary to lower his carbidopa/levodopa dose.

Adverse Effects

CASE 59-1, QUESTION 17: What are the adverse effects of entacapone, and how should they be managed?

Most entacapone-induced adverse effects are consistent with increased levodopa exposure. They include dyskinesias (50%–60%), dizziness (10%–25%), nausea (15%–20%), and hallucinations (1%–14%).[105],[106] Reducing the levodopa dosage by 10% to 15% as a strategy for circumventing these effects is successful in about one-third of patients experiencing dyskinesias. Other adverse effects related to entacapone include urine discoloration (11%–40%), diarrhea (10%), and abdominal pain (6%).[105],[106] Urine discoloration (brownish orange) is attributed to entacapone and its metabolites and is considered benign, but patients should be counseled regarding this effect. The most common reason for withdrawal from clinical studies and discontinuation of therapy was severe diarrhea (2.5%).[107] Although the results of the STRIDE-PD study indicated that patients taking the combination of carbidopa/levodopa/entacapone may be at an increased risk for cardiovascular events (e.g., heart attack, stroke, and cardiovascular death) compared with those taking carbidopa/levodopa, subsequent FDA analysis has found no increased risk.[108]

MONOAMINE OXIDASE-B INHIBITORS

Selegiline

Selegiline may have a role as a symptomatic adjunct to levodopa in more advanced disease. Studies have found improvement in the wearing-off effect in 50% to 70% of patients and a reduction in as much as 30% in the total daily dose of levodopa without improvements in on-time.[109],[110] This improvement has also been shown to arrive with an initial worsening of dyskinesis in 60% of treated patients which may be counteracted with levodopa dose reductions. Selegiline has been shown to reduce off-time by 32% (2.2 hours) compared with 9% (0.6 hours; $P<0.001$) for placebo in a 12-week, randomized, multicenter, parallel-group, double-blind study, but was not reproducible in an identical trial.[111],[112] Authors hypothesize that this conflict may be due in part to large and potentially variable placebo effects seen in PD trials. The on–off effect is less responsive to the addition of selegiline.

Rasagiline

Rasagiline has also been studied as an adjunct to levodopa in advanced disease. When added to levodopa therapy, rasagiline can improve motor fluctuations, reducing off-time by 1.4 hours and 1.8 hours (for the 0.5- and 1-mg/day groups, respectively) compared with 0.9 hours for placebo.[113] Patients treated with 0.5 mg/day and 1 mg/day of rasagiline had 0.49 hour (0.08–0.91; $P = 0.02$) and 0.94 hour (1.36–0.51; $P<0.001$) less off-time compared with placebo. Significant improvements were reported in the UPDRS subscores for ADLs in the off state and motor performance in the on state, as well as clinician global assessments. Dyskinesias were slightly worsened in the 1-mg/day group. As adjunctive therapy to levodopa, rasagiline appears to provide similar benefit to entacapone.[16] In the Lasting effect in Adjunct therapy with Rasagiline Given Once daily (LARGO) study, when compared with entacapone 200 mg administered with each levodopa dose, rasagiline 1 mg/day reduced total daily off-time in a similar manner (decrease of 21% or 1.18 hours for rasagiline and 21% or 1.2 hours for entacapone).[114] Reduction of levodopa dose may be necessary if dyskinesias occur when rasagiline is added in combination with levodopa.

Safinamide

Safinamide (Xadago) was approved by the FDA in May 2017 as an adjunct to carbidopa/levodopa for patients experiencing “off” episodes. It is not approved as monotherapy and thus has not been previously discussed. The side effect profile is similar to rasagiline (see Table 59-2). Patients should additionally be monitored for visual changes as retinal detachment and loss of photoreceptor cells were noted in animal studies. The list of contraindicated medications is extensive and should be reviewed prior to starting therapy. Safinamide has a half–life of 20-26 hours, reaches steady state in 5-6 days, and can be taken without regard to meals. It requires hepatic dose adjustment but no renal dose adjustments. The extent of use in clinical practice and eventual place in therapy are unknown at this time.

Surgical Therapies for PD

CASE 59-1, QUESTION 18: L.M. is now classified as Hoehn and Yahr[2] late stage 3. He is now on amantadine 100 mg twice daily, immediate-release carbidopa/levodopa 25 mg/250 mg 5 times daily, and entacapone 200 mg 5 times daily with carbidopa/levodopa administrations. His overall control of his PD has diminished greatly in the last couple of months. His on-time averages around 6 hours/day, with the majority of it accompanied by troublesome dyskinesias. Most days he needs some assistance with ADLs. His cognitive function remains well preserved, and he is not depressed. He has heard about surgical procedures that might benefit patients with PD. Is surgical therapy superior to medical therapy in patients with advanced PD?

Two types of surgical therapies have been used in patients with advanced PD who cannot be adequately controlled with medications. The first involves making an irreversible surgical lesion in a specific location in the brain (e.g., posteroventral pallidotomy or stereotaxic thalamotomy); the second involves surgical implantation of a device that sends electrical impulses to specific parts of the brain (e.g., deep brain stimulation [DBS]) (Figure 59-5). Posteroventral pallidotomy has been shown to reduce dyskinesias on the contralateral side and may permit the use of higher dosages of levodopa for managing rigidity and bradykinesia.[115] However, a significant disadvantage is the need to make a lesion near the optic tract, which may risk visual loss. Other possible risks of pallidotomy include weakness, paralysis, and hemorrhage that can cause stroke and speech difficulty. Stereotaxic thalamotomy has been shown to reduce symptoms of debilitating tremor and improve rigidity in patients with PD.[116] This intervention has eliminated contralateral tremor in 80% of patients, and improvement has been sustained for up to 10 years. However, as with pallidotomy, a disadvantage of thalamotomy is the need to make an irreversible lesion in the basal ganglia that may limit the effectiveness of newer procedures because they become available. Thus, DBS is now the preferred surgical method for treating advanced PD that cannot be adequately controlled with medications. DBS uses an implanted electrode in the brain, in either the subthalamic nucleus (STN) or the globus pallidus interna (GPi), which is connected to a subcutaneously implanted pacemaker. This permits delivery of high-frequency stimulation to the desired target. Advantages of DBS include no need for an irreversible brain lesion, and it provides flexibility for altering the target site and program stimulation parameters.

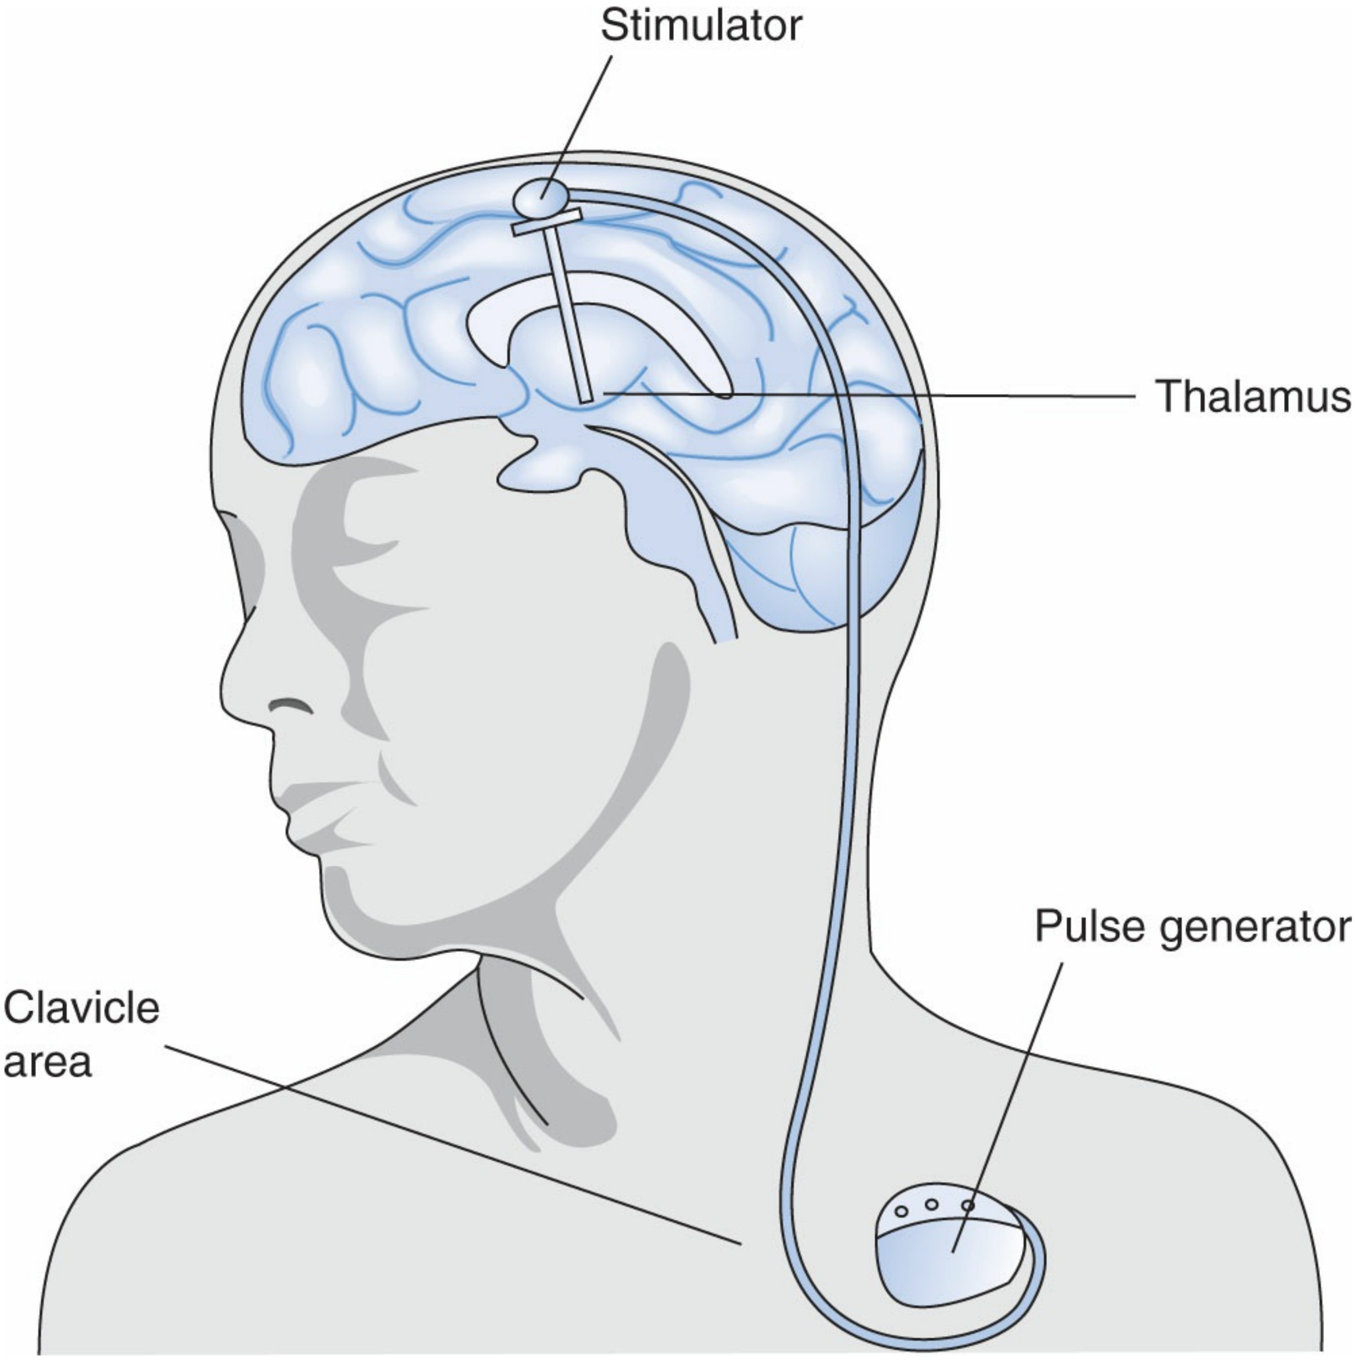

Figure 59-5 Deep brain stimulation. A pulse generator, surgically implanted in a pouch beneath the clavicle, sends high-frequency electrical impulses to the thalamus, thereby blocking the nerve pathways associated with tremors in PD. (Adapted with permission from Smeltzer SC, Bare BG. Textbook of Medical-Surgical Nursing. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2000.)

The efficacy of DBS in advanced PD was shown in a two-part study of 255 patients with idiopathic PD responsive to levodopa but with persistent and disabling motor symptoms.[117] Patients were randomly assigned to DBS or best medical therapy and followed for 6 months. Patients receiving DBS gained a mean of 4.6 hours/day of on-time without troubling dyskinesias compared with 0 hours/day for best medical therapy ($P<0.001$). Additionally, 71% of patients receiving DBS experienced clinically meaningful motor function improvements (≥5-point change in UPDRS motor score) compared with only 32% of patients receiving best medical therapy ($P<0.001$).[117]

CASE 59-1, QUESTION 19: What surgical therapy would be most appropriate for L.M.?

L.M. appears to be an ideal candidate for DBS. Candidates for DBS should have idiopathic PD and be levodopa-responsive, but continue to experience motor complications or tremor despite optimal pharmacotherapeutic regimens. Ideally, DBS should be avoided in patients with preexisting cognitive or psychiatric problems owing to a slight risk of decline in cognition. No strict age limitation for DBS exists, but patients younger than 70 years of age, such as L.M., appear to recover from surgery more quickly and show greater motor improvements. Deep brain stimulation of the STN consistently demonstrates marked reduction in the need for escalating levodopa dosages compared with DBS of the GPi,[118–121] but data suggest other nonmotor symptoms such as visual processing speed and depression may be affected more favorably when targeting the GPi.[118]

Investigational Pharmacotherapy

CASE 59-2

QUESTION 1: K.B. is a 61-year-old woman who presents to the movement disorders clinic after referral from her family doctor for a presumptive diagnosis of PD. She is Hoehn and Yahr[2] stage 1, with slightly decreased arm swing on the left side and unilateral resting hand tremor. Her past medical history is significant for hypertension and mild renal insufficiency (serum creatinine of 1.4 mg/dL). Since her initial visit with her family physician, she has been researching information about different PD treatments from several PD-related websites. Are there any antioxidants, dietary supplements, or other investigational therapies that may benefit K.B.?

ANTIOXIDANTS

Antioxidants have been hypothesized to benefit patients with PD through their ability to act as free radical scavengers. The most comprehensive evaluation of antioxidant therapy for PD comes from the DATATOP study. [109],[122],[123] In this study, patients with early PD were assigned to one of four treatment regimens: α-tocopherol (2,000 international units[IU]/day) and selegiline placebo; selegiline 10 mg/day and α-tocopherol placebo; selegiline and α-tocopherol active treatments; or dual placebos. The primary endpoint was time to requirement of levodopa therapy. After approximately 14 months of follow-up, no difference was seen between the α-tocopherol group and placebo group in time to require levodopa.[123] Thus, despite the theoretic benefit, clinical data are lacking to support the routine use of α-tocopherol, and it would not be recommended in K.B.[124]

COENZYME Q10

Coenzyme Q10 (CoQ_{10}) is an antioxidant involved in the mitochondrial electron transport chain and has been shown to be reduced in patients with PD.[125] A futility analysis in untreated PD patients treated with CoQ_{10} failed to show statistical significance but met the threshold for futility. Two subsequent phase III trials of early PD patients failed to show symptomatic or neuroprotective benefits.[125–127] In an evaluation of 600 patients with early PD, subjects were randomized to receive either 1,200 or 2,400 mg of CoQ_{10} daily in addition to 1,200 IU of α-tocopherol. The study was terminated prematurely due to failure to meet prespecified futility endpoints and trend in adverse outcomes compared to placebo.[127] Due to the lack of data supporting CoQ10, K.B. should be counseled to avoid its use.

CREATINE AND MINOCYCLINE

Similar to CoQ_{10}, creatine is thought to play a role in mitochondrial energy production and has been shown to protect from MPTP-induced dopamine depletion in animal models.[128] Minocycline is an anti-infective agent that also displays anti-inflammatory effects and is hypothesized to alter the neuroinflammatory response that occurs because dopaminergic neurons are lost in PD. Minocycline has been shown to be protective in MPTP animal models of PD.[128]

The use of both creatine and minocycline in PD was examined in a futility-design study, in which patients with early PD not requiring therapy were randomly assigned to receive creatine 10 g/day, minocycline 200 mg/day, or placebo.[128] After 12 months, the mean change in the total UPDRS could not be rejected as futile and met criteria for further clinical testing. A long-term follow-up of this trial found that by 18 months, patients requiring symptomatic treatment did not differ but significantly more patients on minocycline discontinued therapy prematurely (23% vs. 9% of creatine and 6% of placebo patients). Given the unresolved issues surrounding the induction of antibiotic resistance with long-term use of an agent such as minocycline and concerns for tolerability, it is generally not recommended. A long-term, randomized, double-blind, placebo-controlled trial of creatine 10 g/day versus placebo in early treated PD was terminated early for futility based upon an interim analysis. The trial concluded that treatment with creatine for at least 5 years does not support its use in PD.[129] Given the lack of data supporting these agents, they should be avoided in K.B.

FUTURE THERAPIES

With developments in PD research and biopharmaceutical technology, new treatment targets and modalities are constantly being investigated. Such targets include transcription factors, proteins, and their mutations. Novel pharmaceutical and biologic technologies under development include small-molecule drug delivery, such as with glial-cell-derived neurotrophic factor, stem cell therapies, and nerve cell grafts.

Nonmotor Symptoms of Parkinson's Disease

Although PD is mostly recognized for its cardinal features of motor dysfunction, nonmotor symptoms are an important part of the disease throughout all stages and are a key determinant of quality of life.[130] More than 98% of patients with PD have at least one nonmotor symptom; the average per patient is nearly eight, with the number and impact increasing with disease duration and severity.[131] Common nonmotor symptoms include autonomic dysfunction (e.g., gastrointestinal disorders, orthostatic hypotension, sexual dysfunction, urinary incontinence, sialorrhea, seborrhea, and constipation), sleep disorders (e.g., RLS, PLMS, excessive daytime somnolence, insomnia, REM sleep behavior disorder), fatigue, and psychiatric disorders (e.g., dementia, depression, and anxiety).[131] In one longitudinal study of patients with PD, the most common nonmotor symptoms were psychiatric symptoms (68%, most commonly anxiety), fatigue (58%), leg pain (38%), insomnia (37%), urinary symptoms (35%), drooling (31%), and difficulty concentrating (31%).[131] Regular screening for these nonmotor symptoms should occur. L.M. has a history of depression treated with citalopram that could be attributable to PD, and his therapy should be periodically evaluated. The forgetfulness and decreased memory described by L.M. could be early signs of cognitive decline and warrant close observation. The management of several commonly encountered nonmotor symptoms is reviewed below.

DEMENTIA

CASE 59-3

QUESTION 1: J.D. is a 74-year-old man with advanced PD, Hoehn and Yahr[2] stage 4. During the last year, his family has noticed that he is increasingly forgetful and anxious. Twice recently, he left home alone for brief periods, and called 9-1-1 because he thought someone was trying to break into the house. He also calls his daughter 2 or 3 times each day, often repeating the same questions and forgetting that he called her earlier. His wife is his primary caregiver, and he is nearly entirely reliant on her for help in performing ADLs. He scored 20 (below normal) on his most recent Mini-Mental Status Examination, and his family reports that he is no longer interested in social activities or hobbies. Neuropsychiatric testing is performed and demonstrates a significant depressive component to his dementia. Subsequent recommendations from the neuropsychiatrist are that he receives 24-hour supervision, along with participation in structured leisure activities, such as adult day care, several hours/week to help relieve his wife's caregiver burden. How should the progressive cognitive decline that J.D. is experiencing be treated?

The prevalence of dementia in patients with PD is high; 48% to 80% of patients may develop dementia during the disease course, at a rate approximately 6 times greater than healthy individuals.[17],[132] One longitudinal study of 136 incident cases of PD followed for 20 years found that nearly 100% eventually exhibited dementia.[133] The prevalence of cognitive decline and dementia among patients with PD ranges from 10% to 30% and may be associated with a more rapid progression of disease-related disability.[6] Successful management of cognitive impairment in patients with PD first requires that all potentially reversible causes and underlying contributing factors be addressed. These include treating infections, dehydration, and metabolic abnormalities, as well as eliminating unnecessary medications (particularly anticholinergics, sedatives, and anxiolytics) that can exacerbate dementia or delirium.

Experience with cholinesterase inhibitors for treating cognitive impairment in PD indicates marginal improvements with their use.[134–136] Two randomized, controlled trials of donepezil have failed to show consistent benefit, whereas galantamine has only been evaluated in a single open-label trial.[137],[138] Rivastigmine was found to provide clinically meaningful (moderate or marked improvement on the Alzheimer's Disease Cooperative Study–Clinician's Global Impression of Change) benefit to significantly more patients than placebo in a large, randomized, placebo-controlled trial and has demonstrated sustained cognitive benefit for up to 48 weeks.[136],[139],[140] As a result, rivastigmine was FDA-approved for the management of mild-to-moderate dementia in PD and is therefore the drug of choice. Compared with placebo, the cholinesterase inhibitors often result in statistically significant changes on cognitive scales; though, their impact on function and disposition is unclear.

A cholinesterase inhibitor such as rivastigmine may be considered for patients such as J.D., although he must be monitored closely for signs of deterioration of motor function such as worsening of tremor.[137] Cholinesterase inhibitors are associated with other adverse events that may be overlooked and attributed to the PD itself, including sialorrhea, excessive lacrimation, incontinence, nausea, vomiting, and orthostasis. Perhaps more important than any medication therapy, adequate social support for J.D. should be ensured. Because he becomes further dependent on family members for assistance with ADLs, the increased needs of the caregiver(s) should also be considered. In the case of J.D., attending

---

adult day care several times weekly, if available, would provide a structured, supervised environment for interaction with others, as well as providing a rest period for his caregiver. Dementia is a leading cause of nursing home placement for patients with PD.[137]

DEPRESSION/ANXIETY

CASE 59-3, QUESTION 2: How should anxiety and depression be treated in J.D.?

Despite being one of the strongest predictors of quality of life in PD patients, depression is often poorly recognized and inadequately treated.[137] This is likely because depression and PD share overlapping features that often confound the identification of depression. Withdrawal, lack of motivation, flattened affect, decreased physical activity, and bradyphrenia are examples of overlapping features.[137]

Treatment of depression in PD should first focus on providing adequate treatment of the symptoms of PD by attempting to restore mobility and independence, particularly in patients whose depression can be attributed to lengthy off periods. Antiparkinsonian drugs, such as pramipexole, can be associated with mood-enhancing effects independent of their ability to reduce time in the off state.[137] Small trials and case reports have shown that depression in patients with PD can be successfully treated with antidepressant drugs, including tricyclic agents such as amitriptyline, desipramine, nortriptyline, bupropion, and selective serotonin reuptake inhibitors (SSRIs) such as citalopram and paroxetine.[137] Given the overall lack of high-quality trials, it is difficult to know whether expected benefits reflect class responses or are unique to the individual agents studied. Importantly, the potential for adverse effects should always be considered. For example, some SSRIs, such as fluoxetine, can be activating. Although this may be beneficial in patients who are apathetic or withdrawn, it may worsen symptoms in patients with PD who are agitated. Selective serotonin reuptake inhibitors have additionally been noted to worsen PD tremor in approximately 5% of patients.[141] With tricyclic antidepressants, care must be taken to observe for anticholinergic side effects that may worsen PD symptoms, such as impaired cognition, delayed gastric emptying (which may reduce levodopa effectiveness by increasing levodopa degradation in the gut), urinary problems, orthostatic hypotension, and increased risk of falls. Additionally, consideration should be taken for drug interactions and the risk for serotonin syndrome with concomitant MAO-B inhibitors. Electroconvulsive therapy may be considered in refractory cases, but may adversely affect cognition.

Based on his symptoms, it is reasonable to start J.D. on an antidepressant. Clinical experience suggests a good initial choice for balancing efficacy and safety is an SSRI, such as citalopram. As with other patients with depression, the choice of agent should be individualized based on other pragmatic factors such as cost, potential for adverse effects, and personal or family history of response to prior agents. Regardless of which agent or class of antidepressant is selected, therapy should be started at the lowest dose and gradually titrated to effect. He should be monitored closely for side effects, particularly anticholinergic symptoms with tricyclic antidepressants, and for any adverse effects on mobility. He should be observed carefully for changes in parkinsonian symptoms, including development of extrapyramidal symptoms, as well as any signs of psychomotor agitation. Short-term use of benzodiazepines, such as lorazepam or alprazolam, may also provide relief of anxiety symptoms, but must be used cautiously due to adverse effects on cognition and risk of falling.[142] Generally, anxiety symptoms should improve with treatment of the underlying depression.

PSYCHOSIS

In PD, the incidence of psychotic symptoms increases with age, cognitive impairment, and disease duration.[143] Other risk factors include higher age at PD onset, high doses of dopaminergic drugs, and REM sleep behavior disorder.[144] Symptoms are often more pronounced at night (the "sundowning" effect), and hallucinations are typically visual. As with the management of cognitive impairment, it is important to eliminate or minimize any potential causative factors, particularly anticholinergic medications that could be contributing to the hallucinations or delirium. In some patients, reducing the dose of levodopa improves mental function and also provides satisfactory control of motor features. If it is not possible to achieve a balance between preserving motor control and decreasing neuropsychiatric symptoms through reduction in levodopa dosage, antipsychotics may be considered.

Older antipsychotic medications, such as haloperidol, perphenazine, and chlorpromazine, block striatal dopamine D_2 receptors and may exacerbate parkinsonian symptoms. Therefore, these agents are not recommended. Newer atypical antipsychotics are more selective for limbic and cortical D_3, D_4, and D_5 receptors; they have minimal activity at D_2 receptors and may control symptoms without worsening parkinsonism. Of these agents, clozapine has the best evidence of efficacy in patients with PD without adversely affecting motor function and should be preferentially considered.[137] However, its use is complicated by the need for frequent monitoring of white blood cell counts because of the risk of agranulocytosis. Other newer agents, particularly quetiapine, appear promising and have controlled psychosis without worsening parkinsonism.[17],[137] Risperidone and olanzapine have also been studied, but both worsened parkinsonism and were inferior to clozapine in patients with PD.[137],[145] Aripiprazole, also a newer atypical antipsychotic, has been associated with worsening motor function in patients with PD, whereas experience with ziprasidone has yielded mixed results.[146]

AUTONOMIC DYSFUNCTION

Patients with PD frequently experience dysautonomia, including orthostasis, erectile dysfunction, constipation, nocturia, sensory disturbances, dysphagia, seborrhea, and thermoregulatory imbalances. Management of these symptoms is generally supportive, and appropriate medical interventions similar to those used in other geriatric patients can be used to treat these symptoms whenever encountered. In some cases, fludrocortisone or midodrine can be considered if orthostatic hypotension is severe, although these drugs have not been well studied in PD patients specifically.[130] Other possibly effective treatments for symptoms of autonomic dysfunction include sildenafil for erectile dysfunction and polyethylene glycol for constipation.[130]

A new atypical antipsychotic, pimavanserin, was FDA-approved in April 2016 based on results from one randomized, placebo-controlled trial. This agent's mechanism of action is unique, acting through serotonin receptors, and as such it avoids interaction with dopamine receptors responsible for the worsening of PD symptoms with other antipsychotics. It is not without its own risks, including cardiovascular and paradoxical worsening of psychosis.[147]

FALLS

Patients with PD and their caregivers should be counseled on the prevention of falls because they can result in serious morbidity and mortality. Falls generally result from one of several factors, including postural instability, freezing and festination, levodopa-induced dyskinesia, symptomatic orthostatic hypotension, coexisting neurologic or other medical disorders, and environmental factors. Prevention remains the best strategy and includes environmental precautions, such as proper lighting, use of handrails, removing tripping hazards, and incorporating physical and occupational

therapy. Reversible causes of postural or gait instability should be addressed whenever suspected. Patients with PD are advised to take a vitamin D supplement to reduce their risk of fracture with future falls.[17]

SLEEP DISORDERS

Sleep disorders may occur at any time during the disease course and may even precede motor symptom development.[17] In excessive daytime drowsiness, a common sleep disorder in PD, treatment with modafinil may be considered.[130] Other sleep disorders such as insomnia, sleep fragmentation owing to PD symptoms, RLS, and REM sleep disorder (characterized by vivid dreams that are often acted out, especially if frightening) are common and a source of decreased quality of life. When sleep dysfunction can be directly attributed to PD symptoms, such as akinesia, tremor, dyskinesia, or nightmares, dosage adjustment of dopaminergic medications is indicated. Proper sleep hygiene should be encouraged. Insomnia symptoms unrelated to PD symptoms are treated similar to non-PD patients and can be managed supportively.

RESTLESS LEGS SYNDROME AND PERIODIC LIMB MOVEMENTS OF SLEEP

Clinical Presentation

CASE 59-4

QUESTION 1: J.J., a 47-year-old woman, presents to her family physician complaining of daytime fatigue and difficulty sleeping at night because of “jumpy legs.” She reports being able to sleep only 4 to 5 hours/night because of the leg restlessness and feels unrefreshed after sleep. On further questioning, she describes the sensation in her legs as being like "bugs crawling under the skin." The sensation is not painful. She explains that the symptoms worsen in the evening and at night and are partially relieved with walking. She recalls that her mother had similar symptoms. Her spouse notes that she often "kicks" him in her sleep. Review of her medical history shows an otherwise healthy postmenopausal woman. What signs and symptoms are suggestive of RLS in J.J.? What laboratory tests or diagnostic procedures should be performed in J.J. to evaluate her condition?

RLS, also known as Willis–Ekbom disease, is a disabling sensorimotor disorder estimated to affect approximately 2% of the adult population.[148] Although most patients with mild symptoms will not require treatment, RLS can be associated with adverse health outcomes, including sleep-onset insomnia, missed or late work, anxiety, depression, marital discord, and even suicide in severe cases.

Four essential criteria have been established by the International Restless Legs Syndrome Study Group to diagnose RLS (Table 59-6).[149] The pathognomonic trait of RLS is an almost irresistible urge to move the legs (akathisia), often associated with uncomfortable paresthesias or dysesthesias felt deep inside the limbs. Patients describe the sensation as "creepy-crawly" or "like soda water in the veins."[150] The symptoms may occur unilaterally or bilaterally, affecting the ankle, knee, or entire lower limb. With progressive disease, symptoms can begin earlier in the day, and progressive involvement of the arms or trunk may occur. Temporary or partial relief of symptoms can be achieved with movement. If patients attempt to ignore the urge to move the legs, akathisia will progressively intensify until either they move their legs or the legs jerk involuntarily.[150] Symptoms usually manifest in a circadian pattern with onset or worsening during nighttime hours (usually between 6 PM and 4 AM, with peak symptoms between midnight and 4 AM). The circadian pattern persists even in patients with inverted sleep–wake cycles. As a result of their symptoms, patients with RLS become "nightwalkers," spending significant time walking, stretching, or bending the legs in an effort to relieve symptoms.

Table 59-6

Clinical Features of Restless Legs Syndrome (RLS)

Essential Criteria
Urge to move legs, associated with paresthesias or dysesthesias
Relief of symptoms with movement
Onset or exacerbation of symptoms at rest
Onset or worsening of symptoms during nighttime
Supportive Clinical Features
Accompanying sleep disturbance (sleep-onset insomnia)
Periodic leg movements
Positive response to dopaminergic therapy
Positive family history of RLS
Otherwise normal physical examination

RLS, restless legs syndrome.

The symptoms described by J.J. are an example of a classic presentation of RLS.

The prevalence of RLS increases with age and appears to be slightly more common in women.[151] She describes "creepy-crawly" sensations that are relieved partially with walking, a core feature of RLS. Her symptoms are worse during the evening hours. J.J. reports that her mother suffered from similar symptoms. The observation of a familial tendency suggests a genetic component, and several chromosomal loci have been linked to the disease.[152] A strong family history of RLS appears to correlate with an early age of onset (<45 years), whereas presentation at a later age is associated with more neuropathy and accelerated disease progression.[150]

Most cases of RLS are considered primary or idiopathic; therefore, the diagnosis does not require elaborate laboratory tests or diagnostic procedures. Several conditions are associated with RLS and include iron deficiency, pregnancy, and end-stage renal disease. Several medications and substances are known aggravators of RLS, including medications with antidopaminergic properties, such as metoclopramide and prochlorperazine. Nicotine, caffeine, and alcohol can aggravate RLS through their own ability to interfere with quality of sleep. Additionally, SSRIs, tricyclic antidepressants, and commonly used over-the-counter antihistamines, such as diphenhydramine, can trigger or worsen RLS symptoms.[152] Hypotensive akathisia, leg cramps, and other conditions such as arthritis, which can cause positional discomfort with extended periods of sitting in one position, can mimic RLS. These conditions are easily distinguished from RLS because they are usually localized to certain joints or muscles, do not have a circadian pattern, and are not associated with an uncontrollable urge to move.

With an otherwise unremarkable physical examination and medical history, specific laboratory tests that should be performed in J.J. are limited to serum ferritin and percent transferrin saturation (total iron-binding capacity) to rule out iron deficiency anemia. Several studies have documented a relationship between low ferritin concentrations and increased symptom severity.[153] J.J. is postmenopausal, so a pregnancy test is not necessary. Polysomnography is not usually indicated unless there is clinical suspicion for sleep apnea or if sleep remains disrupted despite treatment of

RLS. When clinical suspicion from the physical examination or medical history suggests a possible peripheral nerve or radiculopathy cause, a routine neurologic panel should be obtained.[152] In end-stage renal failure, screening for uremia should be considered because this can trigger symptoms.

CASE 59-4, QUESTION 2: What is the difference between RLS and PLMS?

In addition to the presence of RLS, the symptoms reported by the spouse of J.J. are likely related to PLMS. These are also known as nocturnal myoclonus and are best described as involuntary clonic-type movements of the lower extremities while sleeping that usually involve bilateral ankle dorsiflexion, knee flexion, and hip flexion. Approximately 80% of patients with RLS will also have PLMS, but PLMS can occur by itself and is also associated with significant sleep dysfunction. The diagnosis of PLMS usually requires a polysomnogram; the universally accepted criteria for diagnosis are that there should be at least four periodic leg movements (PLMs) in a 90-second period, with contractions typically lasting 0.5 to 5 seconds and recurring every 5 to 90 seconds.[154] A PLM index (PLMI) is calculated by dividing the total number of PLMs by sleep time in hours; an index of more than 5 but less than 25 is considered mild, a PMLI of more than 25 and less than 50 is moderate, and a PLMI of more than 50 is severe. The diagnosis of PLM disorder can be made when patients present with insomnia, tiredness, and daytime sleepiness in the presence of a high PLMI.[155] There is considerable overlap in the treatments of PLMS and RLS. Because J.J. clearly has RLS, there is no need to perform a polysomnogram. The diagnosis of PLMS in her case is incidental and would not alter the clinical management. An exception to this would be whether her medical history revealed the possibility of sleep apnea, because there is a high association between PLMS and upper airway resistance.[156]

Treatment

CASE 59-4, QUESTION 3: The decision is made to initiate drug therapy in J.J. for the management of her symptoms. What pharmacologic therapy should be selected? What nonpharmacologic therapies should be recommended?

It is important to rule out possible reversible causes before treating RLS. Iron supplements can potentially cure RLS symptoms in patients found to be iron deficient.[157],[158] If J.J. is iron deficient, she should be prescribed 50 to 65 mg of elemental iron 1 to 3 times daily on an empty stomach with 200 mg of vitamin C to enhance absorption. After ruling out possible reversible causes of RLS, it is important to establish the frequency of her symptoms and to select appropriate therapy.

Several classes of medications are effective for treating RLS.[153],[157],[158] Dopaminergic therapies are most consistently effective in relieving RLS symptoms, improving sleep, and reducing leg movements. High-quality evidence has found that levodopa/carbidopa improves RLS symptoms.[153],[157],[158] Dopamine agonists are the preferred dopaminergic class to treat RLS because they are longer acting than levodopa, which allows for more sustained efficacy and control of symptoms throughout the entire night.[153],[157],[158] J.J. should be started on either ropinirole (0.25 mg initially, up to 0.5–4 mg/day) or pramipexole (0.125 mg initially, up to 0.5 mg/day), because both are FDA-approved for treating RLS. Although rotigotine is approved and supported by guidelines, the transdermal formulation may limit use in the early titration phases of RLS management.[50] Several randomized, controlled clinical trials have documented efficacy of these agents in both objective and subjective ratings of improvement by patients and clinicians with either short- or long-term use.[153],[157],[158] Ropinirole and pramipexole do not appear to differ with regard to efficacy or adverse effects. When used for RLS, ropinirole and pramipexole should be administered 2 hours before bedtime. Adverse effects are similar to those seen with the use of these agents in PD, and patients should be counseled accordingly.

Other medications may also provide benefit in RLS. Guidelines recommend the use of pregabalin and gabapentin enacarbil.[153],[157],[158] As a result of their mechanisms of action, these agents may be helpful if JJ had RLS involving neuropathic pain or if she could not tolerate dopaminergic therapy. Though studied, there are inconclusive data to support the use of benzodiazepines, opiates, anticonvulsants, and clonidine.[153],[157],[158] Opiates may be helpful in patients who experience significant pain related to RLS, but these agents have not proven to conclusively treat RLS symptoms.[153],[157],[158] Risks associated with the use of opiates, including respiratory depression and addiction, should be reviewed with the patient prior to initiation. Benzodiazepines and opiates should be avoided in concomitant sleep apnea due to their ability to suppress respiratory drive.

In addition to pharmacologic therapy, nonpharmacologic therapies and behavioral techniques should also be recommended for J.J. Most important among these include discontinuing all RLS aggravators and practicing good sleep hygiene. Physical and mental activity (e.g., reading, playing card games, or working on the computer) if patients are unable to sleep can reduce symptoms.[152] Counter stimuli such as massage or hot baths may also be helpful.[152]

CASE 59-4, QUESTION 4: After carefully considering the costs of therapy, J.J. and her physician choose levodopa to treat her RLS instead of a dopamine agonist. She initially responds well to the therapy. One year later, J.J. returns for follow-up. Her dose of carbidopa/levodopa has progressively increased to three 25 mg/100 mg tablets at bedtime. She describes continued worsening of her symptoms that do not seem to be relieved with increasing doses of carbidopa/levodopa. Her symptoms are now starting earlier in the evening, occur almost every night, and are now painful. How should her therapy be further adjusted?

J.J. is likely experiencing augmentation, a common problem with long-term use of dopaminergic drugs, particularly levodopa.[159] Augmentation is described as a progressive worsening of RLS symptoms after an initial improvement and is manifested by gradually intensified symptoms that occur earlier in the evening and spread to other parts of the body.[160] It is the most common side effect occurring with long-term use (>3 months) of dopaminergic agents, and usually occurs 6 to 18 months after therapy is initiated.[152] Doses of dopaminergic agents are often increased in response; however, with each incremental dose increase, symptoms progress more rapidly until they may occur continuously throughout the day.[152] Although augmentation has been clinically recognized for many years, it has not been systematically studied. The exact etiology is uncertain, but it likely relates to the finding that RLS, unlike PD, is actually a hyperdopaminergic condition with an apparent postsynaptic desensitization that overcompensates during the circadian low point of dopaminergic activity in the evening and night. Adding dopamine in the evening initially corrects the symptoms, but ultimately leads to increasing postsynaptic desensitization.

The highest risk for augmentation is with levodopa. An estimated 50% to 85% of patients on levodopa will develop augmentation, compared with only 20% to 30% with dopamine agonists.[161] The primary treatment strategy for the management of augmentation is to withdraw the dopaminergic agent and substitute this with nondopaminergic agents. Given her presentation, J.J. should have her carbidopa/levodopa discontinued. She should be counseled that her symptoms will likely rebound severely for 48 to 72 hours, but approximately 4 to 7 days later her symptoms should gradually return to baseline or pretreatment state.[152]

With the discontinuation of carbidopa/levodopa in J.J., an alternative therapy should be selected. The selection of an alternative agent in cases in which the initial therapy failed or augmentation occurs must be approached on an individual basis. Although a number of agents are available to choose from, clinical experience generally guides the decision because lack of comparative trials precludes development of any formal recommendations. Because J.J. describes increasing pain with her RLS, it would be appropriate to initiate a trial of gabapentin encarbil or pregabalin. If ineffective or not tolerated, J.J. could be prescribed an opiate to manage her pain. Hydrocodone, oxycodone, methadone, codeine, and tramadol have all been evaluated in RLS.[152] Risks associated with opiate use, including respiratory depression and addiction, should be discussed in detail with J.J. prior to initiation. Augmentation does not prevent a future reintroduction of dopaminergic therapy; in the case of J.J., a dopamine agonist could be added after an extended dopaminergic free period if her symptoms are not completely controlled with nondopaminergic agents or if her symptoms were not painful.

ESSENTIAL TREMOR

Clinical Presentation

CASE 59-5

QUESTION 1: K.H. is a 52-year-old white female office manager who was referred to a neurologist for evaluation of bilateral tremor. She is otherwise healthy and reports not taking any regularly prescribed medications. She describes her tremor as being present mainly when she performs voluntary movements. The tremor is not noticeable during rest. She also notices that the tremor seems to disappear in the evening after drinking a couple of glasses of wine. The tremor interferes with several of her ADLs, including writing, eating, drinking from a cup, and inserting her keys into the ignition. She reports mild interference with her job function and some social embarrassment. No bradykinesia or rigidity is elicited on physical examination. A handwriting sample reveals large characters that are difficult to decipher. Family history reveals that her maternal grandmother and mother both had similar symptoms. What signs and symptoms are consistent with essential tremor in K.H.?

Beginning in the mid-20th century, the term essential tremor (ET) has been consistently used to describe a kinetic tremor for which no definite cause has been established. ET is a common neurologic disorder with an estimated incidence of 616 cases/100,000 person-years, and a prevalence of about 0.9% to 4.6%.[162],[163] Despite its prevalence, it is underrecognized and undertreated, likely because it has been traditionally viewed as a monosymptomatic disorder of little consequence. More recently, it is recognized to be complex and progressive, resulting in significant disability in ADLs and job performance, and social embarrassment.[162] Both the incidence and prevalence of ET increase with age. In addition, ethnicity and family history of ET are consistently identified risk factors; it is approximately 5 times more common in whites than in blacks, and approximately 50% of patients report a positive family history. The latter finding suggests that genetic predisposition may play a role in ET; however, differences in intrafamilial onset and severity suggest environmental factors may also influence underlying susceptibility to the disease. Several environmental toxins have been proposed as causes of ET, including β-carboline alkaloids (e.g., harmane and harmine) and lead, both of which have been found in elevated concentrations in patients with ET compared with normal control subjects.[165],[166]

Because parkinsonian tremor and ET are the most common forms of tremor observed in practice, it is important to distinguish between the two because the treatments differ substantially. Tremor should first be identified as either an action (kinetic, postural, and isometric) or resting tremor. The defining feature of ET is a bilateral, largely symmetrical, 5- to 10-Hz kinetic and postural tremor of the arms. The tremor can also affect the head or voice. The symptoms must be present for greater than 5 years and must not be attributable to other causes such as tremorogenic drugs.[165] Although both kinetic and postural action tremors can be present in ET and PD, the presence of resting tremor is much more common in PD. Lack of resting tremor and absence of bradykinesia or rigidity in K.H. suggest the tremor is not parkinsonian. She describes interference of her tremor occurring with voluntary movement, such as in her ADLs and drinking from a cup. Other signs and symptoms that support a diagnosis of ET include her age, family history, large and tremulous handwriting (as opposed to micrographia in PD), and improvement in tremor with alcohol consumption. Table 59-7 summarizes the similarities and differences of ET and parkinsonian tremor.

Table 59-7

Differentiation of Essential Tremor and Parkinson’s Disease (PD)

Characteristic	Essential Tremor	Parkinson’s Disease
Kinetic tremor in arms, hands, or head	++	++
Hemibody (arm and leg) tremor	0	++
Kinetic tremor > resting tremor	++	+
Resting tremor > kinetic tremor	0	++
Rigidity or bradykinesia	0	++
Postural instability	0	++
Usual age of onset (years)	15–25, 45–55	55–65
Symmetry	Bilateral	Unilateral > bilateral
Family history of tremor	+++	+
Response to alcohol	+++	0
Response to anticholinergics	0	++
Response to levodopa	0	+++
Response to primidone	+++	0
Response to propranolol	+++	+
Handwriting analysis	Large, tremulous script	Micrographia

0, not observed; +, rarely observed; ++, sometimes observed; +++, often observed.

Several medications and substances are known to cause tremor, and all patients should have thorough medication history to rule out these causes. Medications commonly implicated include corticosteroids, metoclopramide, valproate, sympathomimetics (e.g., albuterol, amphetamines, pseudoephedrine), SSRIs, tricyclic antidepressants, theophylline, and thyroid preparations.[167,168] In addition, caffeine, tobacco, and chronic alcohol use can cause tremor that resembles ET. K.H. does not report taking any regularly prescribed medications; however, she should be questioned regarding any over-the-counter medication use as well as her alcohol use and caffeine and smoking habits.

The diagnosis of ET is based solely on clinical examination and neurologic history. Neuroimaging is not useful, and there are no available biologic markers or diagnostic tests that are specific to ET. The evaluation of the tremor that K.H. is experiencing should include laboratory analysis to rule out possible medical conditions associated with tremor. Such conditions may include the presence of hyperthyroidism or Wilson disease (particularly in patients younger than 40 years of age).[167,168]

Treatment

CASE 59-5, QUESTION 2: What therapies are effective in treating ET? How should K.H. be treated?

Patients with ET who have mild disability that does not cause functional impairment or social embarrassment can go without treatment. Because K.H. is experiencing tremor that is interfering with her occupation and causing social embarrassment, she should be considered for pharmacotherapy (Table 59-8). It is important to note that although effective treatments exist, tremor is rarely eliminated completely. Factors predicting lack of response have not been readily identified.

Propranolol, a nonselective β-adrenergic receptor blocker, or primidone, an anticonvulsant, is recommended as first-line agent to treat ET.[169,170] Propranolol is typically effective in doses of at least 120 mg/day, with about 50% of patients having long-lasting benefit.[170,171] Long-acting propranolol is as effective as the regular-release formulation. Other beta-1 (β_1)-selective blockers such as atenolol and metoprolol have also been studied, but with mixed findings.[166,170,171] Propranolol has demonstrated greater efficacy than these β_1-selective agents, suggesting that blockade of β_2 receptors is of importance. β-adrenergic receptor blockers with intrinsic sympathomimetic activity, such as pindolol, appear ineffective in ET.[168–170] Caution should be exercised with propranolol in patients with asthma, congestive heart failure, diabetes mellitus, and atrioventricular block.

Table 59-8

Pharmacotherapy for Essential Tremor

Drug	Initial Dose	Usual Therapeutic Dose	Adverse Effects
β-Blockers			
Propranolol	10 mg every day to BID	120–320 mg divided every day to BID	Bradycardia, fatigue, hypotension, depression, exercise intolerance
Atenolol	12.5–25 mg every day	50–150 mg every day	Bradycardia, fatigue, hypotension, exercise intolerance
Nadolol	40 mg every day	120–240 mg every day	Bradycardia, fatigue, hypotension, exercise intolerance
Anticonvulsants			
Primidone	12.5 mg every day at bedtime	50–750 mg divided every day to TID	Sedation, fatigue, nausea, vomiting, ataxia, dizziness, confusion, vertigo
Gabapentin	300 mg every day in single or divided doses	1,200–3,600 mg divided TID	Nausea, drowsiness, dizziness, unsteadiness, weight gain, peripheral

			edema, potential for abuse
Topiramate	25 mg every day	200–400 mg divided BID	Appetite suppression, weight loss, paresthesias, concentration difficulties
Pregabalin	75 mg BID	75–300 mg divided BID	Weight gain, dizziness, drowsiness, potential for abuse
Benzodiazepines			
Alprazolam	0.125 mg every day	0.75–3 mg divided TID	Sedation, fatigue, ataxia, dizziness, potential for abuse
Clonazepam	0.25 mg every day	0.5–6 mg divided every day to BID	Sedation, fatigue, ataxia, dizziness, impaired cognition, potential for abuse
Miscellaneous			
Botulinum toxin A	Varies by injection site: 50–100 units/arm for hand tremor; 40–400 units/neck for head tremor; 0.6–15 units/vocal cords for voice tremor; repeat no sooner than every 3 months (extend as long as possible)		Hand weakness (with wrist injection); dysphagia, hoarseness, breathiness (with neck or vocal cord injection)

BID, 2 times daily; TID, 3 times daily.

Several studies have compared propranolol and primidone in ET, and they are considered to have similar efficacy.[169–171] Primidone is metabolized to a phenobarbital-based metabolite; however, phenobarbital is inferior to primidone in treating ET.[171] Acute adverse effects of primidone include nausea, vomiting, and ataxia, which can occur in up to one-fourth of patients, often limiting its use.[169] Primidone should be initiated at 12.5 mg/day and administered at bedtime to reduce the occurrence of acute side effects. It can be titrated gradually as tolerated up to 750 mg/day in divided doses, although side effects become more common at doses greater than 500 mg/day.[169]

Other agents that have demonstrated variable efficacy in ET include gabapentin, pregabalin, topiramate, and benzodiazepines (specifically, alprazolam and clonazepam).[170] They are generally considered to be less-proven, second-line therapies. Adverse effects and potential for abuse should be considered when an agent is selected.

If oral pharmacotherapy options for ET are not beneficial, intramuscular injections of botulinum toxin A or surgical treatments can be used in selected patients.[170] Targeted botulinum toxin A injections can reduce hand, head, and voice tremor; however, they are associated with focal weakness of the adjacent areas.[169] Injections in the wrist can cause hand weakness, and dysphagia, hoarseness, and breathiness can occur with injections into the neck or vocal cords. The use of botulinum toxin injections in the United States is also limited by cost. Treatment should occur with the lowest dose, and the interval should be as long as possible between injections. DBS of the ventral intermediate nucleus of the thalamus or unilateral thalamotomy is possibly efficacious in reducing ET.[170] Greater improvement in self-reported measures of function and fewer adverse events make DBS the preferred surgical option of the two.[170]

Because K.H. is otherwise healthy, she is a good candidate for propranolol therapy. Propranolol can be initiated as needed or on a scheduled basis depending on the degree of impairment and desire of the patient. If the decision is made with K.H. to use propranolol on an as-needed basis, she should begin with one-half of a 20-mg tablet administered 30 minutes to 1 hour before the desired effect. The dose can be increased from one-half to two tablets. An example of a situation in which this may occur is whether she wants to avoid embarrassment with attending a social activity or before certain tasks requiring manual dexterity at work. Given the degree of her impairment, she is probably a better candidate for chronic suppressive therapy with propranolol. In this situation, she can be prescribed 10 mg twice daily, because it can be safely and easily up-titrated every few days to a minimally effective dose, generally not more than 120 to 360 mg/day in divided doses.

Seizure Disorders

James W. McAuley and Brian K. Alldredge

CORE PRINCIPLES	CHAPTER CASES
① Epilepsy is a disorder characterized by spontaneously recurring seizures. Seizures can arise from a focal area of the brain (focal or partial seizures) or arise diffusely from both brain hemispheres (primary generalized seizures).	**Case 60-1 (Question 1)**
② The optimal choice of antiepileptic drug (AED) treatment is based on patient-specific considerations including seizure type (or epilepsy syndrome, if defined), age, sex, concomitant medical conditions and therapies, and AED adverse effects. Monotherapy is preferred; polytherapy should be considered for patients with multiple seizure types and/or when monotherapy (with 2 or 3 agents) fails at maximal tolerated doses.	**Case 60-1 (Questions 2, 3),** **Case 60-6 (Question 1),** **Case 60-7 (Questions 1, 3, 4)**
③ Standard AEDs, such as carbamazepine, phenytoin, and valproate, are used commonly for patients with newly diagnosed epilepsy. Newer AEDs (e.g., lacosamide, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, topiramate, zonisamide, ezogabine, perampanel, eslicarbazepine) are often initially approved for add-on therapy in patients with partial-onset seizures who do not respond to other AEDs. Lamotrigine, oxcarbazepine, topiramate, lacosamide, and felbamate are indicated for monotherapy.	**Case 60-1 (Question 3),** **Case 60-2 (Question 1),** **Case 60-6 (Question 1)**
④ Enzyme-inducing AEDs (carbamazepine, phenobarbital, phenytoin) increase the metabolism of many other drugs (e.g., warfarin, contraceptive hormones). In addition, carbamazepine induces its own metabolism and levels may decline during the first month of therapy despite excellent adherence.	**Case 60-1 (Question 5),** **Case 60-11 (Question 1)**
⑤ Serious idiosyncratic adverse effects have been associated with most standard and new AEDs and include carbamazepine-associated hematologic abnormalities; lamotrigine-associated skin rash; valproate-induced hepatotoxicity; and hypersensitivity syndrome seen with carbamazepine, phenobarbital, and phenytoin. The role of routine laboratory monitoring for detection of these adverse effects is controversial. Patients should know the signs or symptoms that should prompt them to seek medical attention.	**Case 60-1 (Question 4),** **Case 60-2 (Question 1),** **Case 60-7 (Questions 8, 9),** **Case 60-10 (Questions 1, 2)**
⑥ Unlike other AEDs, phenytoin displays capacity-limited pharmacokinetics at serum concentrations that are clinically useful for	**Case 60-3 (Questions 2, 3)**

	epilepsy treatment. As a consequence, phenytoin blood levels often change disproportionately to changes in dosage, and time to steady state varies significantly in individual patients based on the phenytoin concentration.	
⑦	Serum concentration monitoring can be useful for selected AEDs when there is a good correlation between concentration and therapeutic or toxic responses. However, clinical criteria (seizure control, medication tolerability) are the primary determinants of the need for dosage adjustments.	**Case 60-7 (Question 7)**
⑧	The occurrence of seizure clusters (acute repetitive seizures) and status epilepticus (prolonged or repeated seizures without recovery of consciousness) warrants emergent AED therapy. Acute repetitive seizures are often treated by parents or caregivers with rectal diazepam. Status epilepticus is a life-threatening emergency and should be treated with intravenous (IV) lorazepam as initial therapy.	**Case 60-8 (Question 1),** **Case 60-12 (Questions 1–4)**

Incidence, Prevalence, and Epidemiology

Approximately 10% of the population will experience a seizure at some time in their life. Up to 30% of all seizures are provoked by central nervous system (CNS) disorders or insults (e.g., meningitis, trauma, tumors, and exposure to toxins); these seizures may become recurrent and require chronic treatment with AEDs. Reversible conditions such as alcohol withdrawal, fever, and metabolic disturbances may provoke acute, isolated seizures. These seizures, along with drug-induced seizures, are not considered to be epilepsy and usually do not require long-term AED therapy. Approximately 1% of the general population has epilepsy.[1]

Terminology, Classification, and Diagnosis of Epilepsies

CLASSIFICATION OF SEIZURES AND EPILEPSIES

A seizure is the “transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain” (p. 471).[2] These signs or symptoms “may include alterations of consciousness, motor, sensory, autonomic, or psychic events” (p. 593).[1] Epilepsy is a “disorder of the brain characterized by an enduring predisposition to generate epileptic seizures and by the neurobiologic, cognitive, psychological and social consequence of this condition” (p. 471).[2] By definition, epilepsy requires the occurrence of two or more seizures that are not acutely provoked by other illnesses or conditions.[3] Guidelines have recently been updated to include a patient who has had one unprovoked seizure and has a high risk

(>60%) of a second seizure to be included in the definition of a person with epilepsy.[4] A commonly used classification scheme for epileptic seizures is shown in Table 60-1.[5] Older terms such as “grand mal” and “petit mal” should not be used, because their use may create confusion in the clinical setting. For example, it is common for patients or caregivers to identify any seizure other than a generalized tonic–clonic seizure as a “petit mal” seizure. This labeling may result in the selection of an inappropriate medication.

Generalized tonic–clonic seizures are common. The patient loses consciousness and falls at the onset. Simultaneously, tonic muscle spasms begin and may be accompanied by a cry that results from air being forced through the larynx. Bilateral, repetitive clonic movements follow. After the clonic phase, patients return to consciousness but remain lethargic and may be confused for varying periods of time (postictal state). Urinary incontinence and tongue biting is common. Primary generalized tonic–clonic seizures affect both cerebral hemispheres from the outset. Secondarily generalized tonic–clonic seizures begin as either simple or complex partial seizures. The aura described by some patients before a generalized tonic–clonic seizure represents an initial partial seizure that spreads to become a secondarily generalized seizure. Identification of secondarily generalized tonic–clonic seizures is important because some AEDs are more effective at controlling primary generalized seizures than secondarily generalized seizures. In general, partial seizures are often more difficult to control with AEDs as compared to primary generalized seizures.[3,6,7]

Absence seizures occur primarily in children and often remit during puberty; affected patients may exhibit a second type of seizure. Absence seizures consist of a brief loss of consciousness, usually lasting several seconds. Simple (typical) absence seizures are not accompanied by motor symptoms; automatisms, muscle twitching, myoclonic jerking, or autonomic manifestations may accompany atypical (complex) absence seizures. Although consciousness is lost, muscle tone is maintained and patients do not fall during absence seizures. Patients are unaware of their surroundings and will have no recall of events during the seizure. Consciousness returns immediately when the seizure ends, and postictal confusion does not occur. Differentiation of atypical absence seizures from complex partial seizures may be difficult if only a second-hand account of the episodes is available; identification of a focal abnormality by an electroencephalogram (EEG) often is necessary to identify complex partial seizures. This distinction is important for the proper selection of AED.

Table 60-1

Classification of Epileptic Seizures

Partial Seizure (Focal)
Simple Partial Seizures (Without Impairment of Consciousness)

Motor symptoms
Special sensory or somatosensory symptoms
Autonomic symptoms
Psychic symptoms
Complex Partial Seizures (With Impairment of Consciousness; “dyscognitive features”)
Progressing to impairment of consciousness
With no other features
With features as in simple partial seizures
With automatisms
With impaired consciousness at onset
With no other features
With features as in simple partial seizures
With automatisms
Partial Seizures That Evolve to Generalized Seizures
Simple partial seizures evolving to generalized seizures
Complex partial seizures evolving to generalized seizures
Simple partial seizures evolving to complex partial seizures to generalized seizures
Generalized Seizures (Convulsive or Nonconvulsive)
Absence Seizures
Typical seizures (impaired consciousness only)
Atypical absence seizures
Myoclonic Seizures
Clonic Seizures
Tonic Seizures
Tonic–Clonic Seizures
Atonic (Astatic or Akinetic) Seizures
Unclassified Epileptic Seizures
All seizures that cannot be classified because of inadequate or incomplete data and some that cannot be classified in previously described categories

Simple partial (focal motor or sensory) seizures are localized in a single cerebral hemisphere or portion of a hemisphere. Consciousness is not impaired during these events. Various motor, sensory, or psychic manifestations may occur depending on the area of the brain that is affected. A single part of the body may twitch, or the patient may experience only an unusual sensory experience.

Complex partial seizures result from the spread of focal discharges to involve a larger area. Consciousness is impaired and patients may exhibit complex but inappropriate behavior (automatisms) such as lip smacking, picking at clothing, or aimless wandering. A period of brief postictal lethargy or confusion is common.

In 2010, the International League Against Epilepsy recommended modifications to the traditional seizure classification scheme and terminology. Whereas some of the terminology remained unchanged, seizures limited to one hemisphere are now termed “focal seizures” (instead of partial seizures) and the formal distinction between complex partial and simple partial seizures is eliminated.[8] Because most of the existing literature on epilepsy makes use of the traditional seizure terminology, we have retained the use of “partial,” “complex partial,” and “simple partial” for this chapter.

EPILEPSY SYNDROMES

Epilepsy can be classified based on seizure type as shown in Table 60-1. Epilepsy syndromes can be defined on the basis of seizure type as well as cause (if known), precipitating factors, age of onset, characteristic EEG patterns, severity, chronicity, family history, and prognosis. Accurate diagnosis of epilepsy syndromes may better guide clinicians regarding the need for drug therapy, the choice of appropriate medication, and the likelihood of successful treatment.[1],[6],[7] Many epilepsy syndromes have been defined; a complete listing is beyond the scope of this chapter. Several are of interest with respect to pharmacotherapy and are described in Table 60-2.[7]

Diagnosis

Optimal treatment of seizure disorders requires accurate classification (diagnosis) of seizure type and appropriate choice and use of medications. Seizure classification may be straightforward if an adequate history and description of the clinical seizure are available. Physicians often do not observe patients’ seizures; thus, family members, teachers, nurses, and others who have frequent direct contact with patients should learn to observe accurately and objectively describe and record these events. The onset, duration, and characteristics of a seizure should be described as completely as possible. Several aspects of the events surrounding a seizure may be especially significant: the patient’s behavior before the seizure (e.g., Did the patient complain of feeling ill or describe an unusual sensation?), deviation of the eyes or head to one side or localization of convulsive activity to one portion of the body, impaired consciousness, loss of continence, and the patient’s behavior after the seizure (e.g., Was there any postictal confusion?). In addition, it is helpful if the observer can record the length of the event and how long it took for the patient to return to baseline. A video of the event could be especially helpful. The patient and caregivers should have a seizure calendar or diary to record events. Many options exist to track seizures including online sites and smart phone applications. Those who observe a seizure should not try to label the seizure but should be encouraged to describe the event fully and objectively.

Accurate seizure diagnosis and identification of the type of epilepsy or epilepsy syndrome also depend on neurologic examination, medical history, and diagnostic techniques, such as EEG, computed tomography (CT), and magnetic resonance imaging (MRI). The EEG often is critical for identifying specific seizure types. CT scanning may help assess newly diagnosed patients, but MRI is preferred. MRI may locate brain lesions or anatomic defects that are missed by conventional radiographs or CT scans.[9]

Table 60-2

Selected Epilepsy Syndromes

Syndrome	Seizure Patterns and Characteristics	Preferred AED Therapy	Comments
Juvenile myoclonic epilepsy	Myoclonic seizures often precede generalized tonic–clonic seizures. ↓ sleep, fatigue, and alcohol commonly precipitate seizures	Valproate. Levetiracetam FDA-approved as adjunct for myoclonic seizures. Lamotrigine, topiramate, and zonisamide may be effective	5%–10% of all epilepsies; 85%–90% response to valproate. Lifelong therapy usually needed. High relapse rate with attempts to discontinue AED therapy
Lennox–Gastaut syndrome	Generalized seizures: atypical absence, atonic/akinetic, myoclonic, and tonic most common. Abnormal interictal EEG with slow spike-wave pattern. Cognitive dysfunction and mental retardation. Status epilepticus common	Valproate and benzodiazepines may be effective. Lamotrigine, rufinamide, topiramate and clobazam FDA-approved. Felbamate also may be effective, but potential hematologic toxicity limits use. Poorly responsive to AED	Oversedation with aggressive AED trials may ↑ seizure frequency. Tolerance to benzodiazepines limits their usefulness
Childhood absence epilepsy	Typical absences often in clusters of multiple seizures. Tonic–clonic seizures in ˜40%. Onset usually between ages 4 and 8 years. Significant genetic component. EEG shows classic 3-Hz spike-and-wave pattern	Ethosuximide or valproate. Lamotrigine less effective	80%–90% response rate to AED therapy. Good prognosis for remission. Tonic–clonic seizures may persist
Mesial temporal lobe epilepsy	Complex partial seizures with automatisms. Simple partial seizures (auras) common; secondary generalized seizures occur in 50%	Carbamazepine, phenytoin, valproate, gabapentin, lamotrigine, topiramate, tiagabine, levetiracetam, oxcarbazepine, zonisamide, pregabalin, lacosamide, perampanel, ezogabine, eslicarbazepine	Often incompletely controlled with current AEDs. Emotional stress may precipitate seizures; surgical resection can be effective when patient is identified as a good surgical candidate

AED, antiepileptic drug; EEG, electroencephalogram; FDA, US Food and Drug Administration.

Treatment

Early control of epileptic seizures is important because it allows normalization of patients' lives and prevents acute physical harm and long-term morbidity associated with recurrent seizures. In addition, early control of tonic–clonic seizures is associated with a reduced likelihood of seizure recurrence. Early control of epileptic seizures also correlates with successful discontinuation of AED treatment after long-term seizure control.[10–12]

NONPHARMACOLOGIC TREATMENT OF EPILEPSY

Alternatives or adjuncts to pharmacotherapy may be helpful in some patients. Surgery is an extremely effective treatment in selected patients. Depending on the epilepsy syndrome and procedure performed, up to 90% of patients treated surgically may improve or become seizure-free. A study of 80 patients with medically refractory temporal lobe epilepsy randomly assigned to either surgery or continued medical treatment showed that after 1 year patients were more likely to be seizure-free after surgery.[13] Surgery is advocated as early therapy for some patients with specific epilepsy syndromes, such as mesial temporal sclerosis. Early surgical intervention may prevent or lessen neurologic deterioration and developmental delay.

Dietary modification may be used for patients who cannot tolerate AEDs or to treat seizures that are not completely responsive to AEDs. In most circumstances, dietary modification consists of a ketogenic diet. This low-carbohydrate, high-fat diet results in persistent ketosis, which is believed to play a major role in the therapeutic effect. Ketogenic diets seem to be most beneficial in children; they are also used as adjuncts to ongoing AED treatment.[14],[15]

The vagus nerve stimulator is an implantable device approved for treatment of intractable partial seizures. This device uses electrodes attached around the left branch of the vagus nerve. The electrodes are attached to a programmable stimulator that delivers stimuli on a regular cycling basis; patients can also use "on demand" stimulation at the onset of seizures by swiping the magnet over the subcutaneously implanted stimulator. Approximately 30% to 40% of patients who are so treated have a positive response (50% reduction in seizures).[16] The primary side effect of this device is hoarseness during stimulation; infrequently, this is accompanied by left vocal cord paralysis.

Responsive neurostimulation is a newer non-pharmacologic option for treating intractable partial-onset seizures. Its role in therapy is yet to be determined.

Avoidance of Potential Seizure Precipitants

It is impossible to generalize about environmental and lifestyle precipitants of seizure activity in persons with epilepsy. Individual patients or caregivers may identify specific circumstances such as stress, sleep deprivation, acute illness, or ingestion of excessive amounts of caffeine or alcohol, which may increase the likelihood of a recurrent seizure event. Some women experience an increase in the frequency and/or severity of seizures around the time of menstruation or ovulation. Patients with epilepsy should avoid activities that seem to precipitate seizures; as always, the goal is complete seizure control with as little alteration in quality of life as possible.

ANTIEPILEPTIC DRUG THERAPY

Pharmacotherapy is the mainstay of treatment for epilepsy. Therefore, patient education regarding medications and consultation among health care professionals regarding the optimal use of AEDs are essential to quality patient care. Optimal AED therapy completely controls seizures in approximately two-thirds of patients.[17],[18] Optimization of drug therapy depends on several factors, with the choice of appropriate AED, individualization of dosing, and adherence being the most important.

Choice of Antiepileptic Drug

Many AEDs have a relatively narrow spectrum of efficacy against selected seizure types; therefore, choice of appropriate drug therapy for a specific patient depends on an accurate diagnosis of epilepsy. In addition, toxicity must be considered when selecting an AED. Preferred drugs for specific types of seizures and common epileptic syndromes are listed in Tables 60-2 and 60-3. Although certain drugs are preferred, the identification of the most effective drug for a particular patient may be a process of trial and error; several medication trials may be necessary before success is achieved. It is important to keep in mind that certain AEDs can worsen seizures.[19]

The consensus method was used to analyze expert opinion on treatment of three epilepsy syndromes and status epilepticus.[20] The experts recommended monotherapy first, followed by a second monotherapy agent if the first failed. If the second monotherapy failed, the experts were not in agreement on whether to try a third monotherapy agent or to combine two therapies. The experts recommended epilepsy surgery evaluation after the third failed AED for patients with symptomatic localization-related epilepsies.

To assess the evidence on efficacy, tolerability, and safety of many of the new AEDs in treating children and adults with new-onset and refractory partial and generalized epilepsies, a panel evaluated the available evidence.[21],[22] They concluded that AED choice depends on seizure and syndrome type; patient age; concomitant medications; and AED tolerability, safety, and efficacy. The results of these two evidence-based assessments provide guidelines for the use of newer AEDs in patients with new-onset and refractory epilepsy.

Therapeutic End Points

The individual patient’s response to AED treatment (i.e., seizure frequency and severity, and symptoms of toxicity) must be the major focus for therapy assessment.

In general, the goal of AED treatment is administration of sufficient medication to completely prevent seizures without producing significant toxicity.[23] Realistically, this goal may be compromised for many patients; it may not be possible to completely prevent seizures without producing intolerable adverse effects. Thus, the therapeutic end points achieved can vary among patients; optimization of AED therapy for a specific person depends on tailoring therapy to the patient's needs and lifestyle. It is rarely optimal to administer "standard" or "usual" doses of an AED to a patient or to adjust doses to achieve a "therapeutic blood level" without considering the effect of the dose or serum concentration on the patient's condition and quality of life. As with many conditions requiring chronic drug therapy, patient participation in developing and evaluating a therapeutic plan is extremely important. Patients should be educated regarding the expected positive and negative effects of their AED therapy, and they must be encouraged to communicate with their health care provider regarding their responses to prescribed AEDs.

Table 60-3

Antiepileptic Drugs (AEDs) Useful for Various Seizure Types

Primary Generalized Tonic–Clonic	Secondarily Generalized Tonic–Clonic	Simple or Complex Partial (Focal)	Absence	Myoclonic, Atonic/Akinetic
Most Effective With Least Toxicity[a]				
Valproate	Carbamazepine	Carbamazepine	Ethosuximide	Valproate
Levetiracetam	Oxcarbazepine	Oxcarbazepine	Valproate	Clonazepam
Lamotrigine	Levetiracetam	Levetiracetam	Lamotrigine	Rufinamide (Lennox–Gastaut Syndrome)
Levetiracetam	Lamotrigine	Lamotrigine	(Topiramate)[b]	Levetiracetam (Juvenile Myoclonic Epilepsy)
Levetiracetam	Valproate	Valproate		Lamotrigine[b]
Levetiracetam	Gabapentin	Gabapentin		Clobazam (Lennox–Gastaut Syndrome)
(Oxcarbazepine)[b]	Topiramate			(Topiramate)[b]
Perampanel	Tiagabine Zonisamide Levetiracetam Pregabalin Lacosamide Ezogabine Perampanel	Topiramate[b] Tiagabine Pregabalin Zonisamide Lacosamide Ezogabine Perampanel		

	Eslicarbazepine	Eslicarbazepine		
Effective, but Often Poorly Tolerated or Cause Unacceptable Toxicity				
Phenobarbital	Phenobarbital	Clorazepate	Clonazepam	(Felbamate)[c]
Primidone	Primidone	Phenobarbital		
(Felbamate)[c]	(Felbamate)[c]	Primidone		
Phenytoin	Phenytoin (Vigabatrin)[d]	(Felbamate)[c] Phenytoin (Vigabatrin)[d]		

[a] Drugs are listed in general order of preference within each category. Recommendations by various authorities may differ. The use of phenobarbital and primidone is discouraged.

[b] The place of some AEDs for select seizure types is yet to be determined. More clinical experience is needed before their roles as possible primary AEDs are clarified.

[c] Felbamate is placed on this table only to indicate the types of seizures for which it appears to be effective. Felbamate has been associated with aplastic anemia and hepatic failure; until a possible causative role is clarified, felbamate cannot be recommended for treatment of epilepsy unless all other, potentially less toxic, treatment options have been exhausted.

[d] Vigabatrin causes progressive and permanent visual field constriction that is related to total dose and duration of exposure. Vigabatrin cannot be recommended for treatment of epilepsy unless other potentially less toxic treatment options have been exhausted.

Serum Drug Concentrations

Relation to Clinical Response

For selected AEDs, proper use and interpretation of serum concentrations are important for optimizing treatment regimens in epilepsy.[24,25] An individual patient’s clinical response to AED treatment must be the major focus for therapy assessment. Individual patients often differ dramatically in their response to a particular serum drug concentration; therefore, therapeutic serum concentrations should be considered only as guidelines for treatment. Many patients’ condition may be controlled with serum drug concentrations above or below the usual therapeutic range.[26] In these patients, dosage adjustment to get the patient “in range” is not warranted. It is better to “treat the patient, not the level.”

Interestingly, a recent Cochrane Review found no evidence that measuring AED concentrations routinely to inform dose adjustments is superior to dose adjustments based on clinical information.[27] However, the authors do state that their review does not exclude the possibility that AED serum concentration might be useful in special situations or in selected patients.

Indications for Use

Measurement of serum drug concentrations may provide clinically useful information in the following situations:

- Uncontrolled seizures despite administration of greater-than-average doses: Serum concentrations of AED may help distinguish drug resistance from subtherapeutic drug concentrations caused by malabsorption, nonadherence, or rapid metabolism.

- Seizure recurrence in a patient whose seizures were previously controlled: This is often owing to nonadherence with the prescribed medication regimen.
- Documentation of intoxication: In patients who exhibit signs or symptoms of dose-related AED toxicity, documentation of the dose and serum concentration of the responsible drug is helpful.

- Assessment of patient adherence: Although monitoring AED serum concentrations can be used to assess patient adherence with therapy, conclusions must be based on comparisons with previous steady state serum concentrations that reflected reliable intake of a given dose of AED.
- Documentation of desired results from a dose change or other therapeutic maneuve (e.g., administration of a loading dose): When patients are receiving multiple AEDs, it is often appropriate to measure serum concentrations of all drugs after a change in the dose of one agent because changes to one drug frequently affect the pharmacokinetic disposition of other drugs.
- When precise dosage changes are required: On occasion, small changes in the dos of a drug (e.g., phenytoin) can result in large changes in both the serum concentration and clinical response. In addition, cautious titration of dosage and serum concentration may be necessary to avoid intoxication. Knowledge of the serum drug concentration before the dosage change may allow the clinician to select a more appropriate new maintenance dose.
- During pregnancy, AED serum concentrations often decline and dosage adjustment may be warranted to maintain adequate seizure protection. Free (unbound) concentrations should be monitored for highly protein-bound AEDs. AED serum concentrations should be monitored after delivery, particularly when dosage escalations have been made during pregnancy.

Frequent, “routine” determinations of serum AED concentrations are costly and not warranted for patients whose clinical status is stable. Clinicians may tend to focus attention on normal variability in serum concentrations rather than on the patient’s clinical status; as a result, unnecessary dosage adjustments may be made to make serum concentrations fit the “normal range.” A plan of action for what the clinician is going to do with the information once it is obtained should be in place before obtaining the sample. Therefore, the results of individual serum concentration determinations must be evaluated carefully to decide whether a significant, clinically meaningful change has occurred.[28]

Interpretation of Serum Concentrations

Several factors can alter the relationship between AED serum concentration and the patient's response to the drug. Whenever a change in serum concentration is apparent, pharmacokinetic factors (Table 60-4) should be considered (along with the patient's clinical status) before a decision is made to adjust the AED dosage. Laboratory variability can cause minor fluctuations in reported AED serum concentrations. Under the best conditions, reported values for serum concentrations may be within plus or minus 10% of "true" values.[29],[30] Therefore, the magnitude of any apparent change must be considered. Published therapeutic ranges may have been determined in small numbers of patients or may more accurately represent average serum concentrations at usual doses. Inappropriate sample timing can result in inconsistent and clinically meaningless changes in AED serum concentrations.[24] Generally, serum concentrations of AED should not be measured until a minimum of four to five half-lives have elapsed since initiation of therapy or a dosage change. Blood samples should be obtained in the morning, before any doses of the AED have been taken; this practice provides reproducible, postabsorptive (i.e., "trough") serum concentrations. Interindividual variability in response to a given serum concentration of medication is common. Excellent therapeutic response or even symptoms of intoxication may be associated with AED serum concentrations that are classified as "subtherapeutic."[31] Binding to serum proteins is significant for some AEDs (e.g., phenytoin, valproate, tiagabine). Changes in protein binding can result from drug interaction, renal failure, pregnancy, or changes in nutritional status. These changes can alter the usual relationship between the measured total drug concentration (bound and unbound to plasma proteins) and the unbound (pharmacologically active) drug concentration. This change may not be apparent when only total serum concentrations are measured. Determination of serum concentrations of free (i.e., unbound) AEDs is available from many commercial laboratories; these determinations are expensive and results may not be available for several days. If significant changes in protein binding are suspected, measurement of free concentrations of AED may provide additional information useful for adjustment of doses or interpretation of the patient's symptoms.[29],[30],[32]

Monotherapy Versus Polytherapy

Decades ago, epilepsy was often treated initially with multiple AEDs (polytherapy). A second, third, or even fourth drug was added when seizures were incompletely controlled with a single AED. Evaluation of the effectiveness of polytherapy in subsequent years has shown little advantage for most patients. Use of a single drug at optimal tolerated serum concentrations produces excellent therapeutic results and minimal side effects in most patients. Addition of a second AED significantly improves seizure control in only 10% to 20% of patients.[33],[34] Reduction or elimination of existing polytherapy in patients with longstanding seizure disorders often lessens or eliminates cognitive impairment and other side effects; seizure control actually may improve.[33],[35–38]

Most experts advocate the use of a single AED (monotherapy) whenever possible. Successful monotherapy may require higher-than-usual AED doses or serum concentrations greater than the upper limit of the usual therapeutic range.[39],[40] Addition of a second drug may be necessary in some patients; however, polytherapy should be reserved for patients with multiple seizure types or for patients in whom first-line AEDs have failed to control seizures when titrated to maximal tolerated doses.[20],[36],[39] When a new AED is added to a patient's regimen with the goal of improving seizure control, the existing AED regimen should be scrutinized for continued value. In some cases, a patient's AED regimen can accumulate drugs that may be unnecessary because they were started and never re-evaluated. Continued vigilance and critical assessment of every drug in a patient's regimen is important.

Use of polytherapy creates several disadvantages that must be weighed against possible benefits. Seizure control may not significantly improve. Health care costs, for medications and for increased laboratory monitoring, may increase significantly with polytherapy. In addition, drug interactions among AEDs can complicate assessment of the patient's response and serum concentrations. Patient adherence often is worsened when multiple medications are prescribed, and adverse effects often increase.

Although AED monotherapy is preferred whenever feasible, the recent introduction of several new AEDs has increased the use of polytherapy.[40] Owing to limitations on the patient populations used for clinical trials of new drugs (i.e., patients with seizure disorders not completely controlled by previous medications), most new AEDs are labeled only for use as add-on therapy. Although reports exist on the efficacy of the new AEDs as monotherapy,[41–44] only felbamate, lacosamide, lamotrigine, oxcarbazepine, and topiramate are US Food and Drug Administration (FDA) approved for monotherapy. More AEDs will undoubtedly follow with monotherapy indications.

Duration of Therapy and Discontinuation of Antiepileptic Drugs

A diagnosis of epilepsy may not necessitate lifelong drug therapy. Several long-term studies have shown that AED therapy may be successfully withdrawn from some patients after a seizure-free period of 2 to 5 years.[10–12] Seizures recurred in only 12% to 36% of patients who were followed for up to 23 years after AED withdrawal. Therefore, many patients whose epilepsy is completely controlled with medication can stop therapy after a seizure-free period of at least 2 years.

Table 60-4

Pharmacokinetic Properties of Antiepileptic Drugs (AEDs)

Drug	Oral Absorption (%)	Half-Life (hours)	Time to Steady State[a]	Dosage Schedule	Usual Therapeutic Serum Concentration	Plasma Protein Binding (%)	Volume of Distribution (L/kg)
Carbamazepine	90–100	Chronic: 5–25	2–4 days	BID to TID	5–12 mcg/mL	75 (50–90)	0.8–1.6
Eslicarbazepine	>90	Normal renal function: 13–20	4–5 days	QD	Not determined	<40	0.8
Ethosuximide	90–100	Pediatric: 30Adult: 60	5–10 days	Daily (BID)	40–100 mcg/mL	0	0.7
Ezogabine	60	Normal renal and hepatic function: 7–11	2–4 days	TID	Not determined	80	2–3
Felbamate	90	12–20	3–4 days	BID to TID	50–110 mcg/mL	24	0.7–0.8
Gabapentin	40–60; ↓ with ↑ dose	Normal renal function: 5–9; ↑ with ↓ renal function	Normal renal function: 1–1.5 days	TID to QID (every 6–8 hours)	2 mcg/mL (proposed)	0	≈0.8
Lacosamide	100	13 ↑ slightly with renal impairment	2–3 days	BID	Not determined	<15	0.6
Lamotrigine	90–100	Monotherapy: 24–29Enzyme inducers: 15Enzyme inhibitor (VPA): 59	4–9 days	BID	4–18 mcg/mL (proposed)	55	0.9–1.2
Levetiracetam	100	Normal renal function: 6–8; ↑ with ↓ renal function	Normal renal function: 1–1.5 days	BID	Not determined	<10	≈0.7
Oxcarbazepine	100	8–13	2–3 days	BID to TID	Not determined	40	
Perampanel	100	Normal hepatic function: 105	2–3 weeks	QD	Not determined	95	NA
Phenobarbital	90–100	2–4 days	8–16 days	Daily	15–40 mcg/mL	50	0.5–0.6
Phenytoin	90–100	Varies with dose	5–30 days	Daily to BID	10–20 mcg/mL	95	0.5–0.7
Pregabalin	≥90	Normal renal function: 6; ↑ with ↓ renal function	24 hours	BID to TID	Not determined	0	0.5

Rufinamide	85	9	1–2 days	BID	Not determined	<35	Dose dependent
Tiagabine	90	Monotherapy: 7–9Enzyme inducers: 4–7	1–2 days	BID to QID	Not determined	96	1.1
Topiramate	≥80	12–24	3–4 days	BID	Not determined	10–15	0.7
Valproate	100 (≈80% with divalproex ER)	10–16	2–3 days	BID to QID (daily with divalproex × ER)	50–150 mcg/mL	90+	0.09–0.17
Vigabatrin	80–90	8–12 (not clinically important. Irreversible enzyme inhibitor)	NA	Daily to BID	NA	NA	NA
Zonisamide	≈80	Monotherapy: ≈60Enzyme inducers: 27–36	2 weeks	Daily to BID	Not determined	50–60	1.3

[a] Based on four half-lives. This lag time should allow determination of steady state serum concentrations within limits of most assay sensitivities.

BID, twice daily; NA, not available; TID, three times daily; QID, four times daily; VPA, valproic acid.

Table 60-5

Risk Factors Possibly Predicting Seizure Recurrence After Antiepileptic Drug (AED) Withdrawal

- <2 years seizure-free before withdrawal
- Onset of seizures after age 12
- History of atypical febrile seizures
- Family history of seizures
- 2–6 years before seizures controlled
- Large number of seizures (>30) before control or total of >100 seizures
- Partial seizures (simple or complex)
- Abnormal EEG persisting throughout treatment
- Slowing on EEG before medication withdrawal
- Organic neurologic disorder
- Moderate to severe mental retardation

EEG, electroencephalogram.

Discontinuation of medications is advantageous for economic, medical, and psychosocial reasons. Costs associated with health care visits, serum concentration determinations, and the medications themselves are eliminated or reduced. The risk of adverse effects from long-term medication use is eliminated, and patients can expect fewer lifestyle restrictions. Attempts to withdraw AED therapy are associated with risks, however. Primary among them is the reappearance of seizure activity, which can result in status epilepticus, loss of driving privileges, employment difficulties, and/or physical injury.

Risk factors for seizure recurrence after discontinuation of AED have been identified in observational studies; complete agreement, however, is not found among studies regarding the nature and importance of specific risk factors. Opinions and data also differ regarding the optimal duration of the seizure-free period before discontinuation of AED is attempted. Nevertheless, at least some consensus has been reached regarding certain factors that may predict a higher risk of seizure recurrence (Table 60-5).[10–12,45,46]

In nonemergency situations, AED should be withdrawn slowly; if a patient receives multiple drugs, each drug should be withdrawn separately. Too-rapid withdrawal can result in status epilepticus. Clinical studies of AED discontinuation usually used a 2- to 3-month withdrawal schedule for each drug. The optimal rate of withdrawal of AED has not been identified. One study compared withdrawal of individual drugs for a 6-week and a 9-month period and found no difference in seizure recurrence between the groups.[47] Another study compared seizure frequencies in patients withdrawn from carbamazepine rapidly (for 4 days) and in patients withdrawn more slowly (for 10 days).[48] Significantly more generalized tonic–clonic seizures occurred when carbamazepine was withdrawn rapidly; complex partial seizures, however, did not occur at a higher rate with rapid withdrawal. Therefore, withdrawal of each AED for at least 6 weeks would seem to be a safe approach. Gradual withdrawal is recommended even for medications such as phenobarbital that have long half-lives and should theoretically be "self-tapering." In our experience, gradual reduction of medications such as phenobarbital is associated with a significantly higher success rate. If AEDs are withdrawn at an appropriate rate and seizures recur, drug treatment is usually reinstituted. In most patients, good seizure control is regained by restarting therapy. However, approximately 1% of patients had recurrent seizures that could not be controlled again with AEDs.[49] This uncommon, but potentially serious, outcome should be considered when therapy withdrawal is considered.

CLINICAL ASSESSMENT AND TREATMENT OF EPILEPSY

Complex Partial Seizures with Secondary Generalization

DIAGNOSIS

CASE 60-1

QUESTION 1: A.R. is a 14-year-old, 40-kg female high school student. A.R. had three febrile seizures when she was 3 years old. She received phenobarbital prophylaxis "off and on," according to her parents, for about 6 months after her second febrile seizure. Since then, she had no reported seizures until 24 hours before admission. At that time she had a "convulsion" shortly after arriving at school in the morning. A teacher who witnessed the episode describes her as behaving "oddly" before the seizure. She abruptly got up from her desk and began to walk clumsily toward the door; she bumped into several desks and did not respond to the teacher's attempts to redirect her back to her seat. After approximately 1 minute of this behavior, she fell to the floor and experienced an apparent generalized tonic–clonic seizure that lasted approximately 90 seconds. During the episode, she was incontinent of urine and was described as "turning kind of blue." After this episode, A.R. was transported to the hospital.

On arrival at the hospital, A.R. appeared drowsy and confused. Laboratory studies—a complete blood count (CBC), serum glucose, electrolytes, drug and alcohol screen, and lumbar puncture—were normal. Physical examination and a complete neurologic evaluation were normal. An EEG showed diffuse slowing with focal epileptiform discharges in the left temporal area; it was interpreted as abnormal. There was no history of recent illness or injury, although A.R. had stayed up late several nights recently studying for an examination.

A second seizure occurred in the hospital. The nursing staff described an episode similar to the one that occurred at school. After recovery from each episode, A.R. had no memory of events during the seizures; she only remembered a "funny feeling" in her stomach and a "buzzing" in her head before she lost consciousness. She described having these feelings "a couple of times" in the past; she attributed them to "just getting dizzy" and had not reported them to her parents. After these previous episodes, A.R. described feeling "mixed up" and groggy for a few minutes. What subjective and objective features of A.R.'s seizures are consistent with a diagnosis of complex partial seizures with secondary generalization?

A.R.'s clinical pattern of observed seizure activity (an apparent aura preceding her loss of consciousness), her history of apparent complex partial seizures not accompanied by generalized seizures, and the findings of focal abnormal activity on EEG are all concordant with this diagnosis. Postictal confusion and grogginess are common after both generalized tonic–clonic and complex partial seizures. Her unusual or inappropriate behavior represents a complex partial seizure that subsequently generalized. The clinical features, accompanied by her EEG findings, also help rule out possible atypical absence seizures, which can be confused with complex partial epilepsy syndromes based on only clinical presentation. In both syndromes, patients may briefly appear to lose contact with their surroundings and display automatisms and mild clonic movements during seizure activity. In A.R.'s case, the EEG and the generalized tonic–clonic seizures during her episodes would rule out atypical absence as a likely possibility.

DECISION TO USE ANTIEPILEPTIC DRUG THERAPY

CASE 60-1, QUESTION 2: What factors should be considered in a decision to treat A.R.'s seizures with AED therapy?

Once a diagnosis of epilepsy is established, the decision to treat the patient with medication is based on the likelihood of recurrence. The need for AED therapy after a single seizure is controversial, but according to the 2015 evidenced-based guideline on this topic, patients should be informed that their seizure recurrence risk is greatest early within the first 2 years and starting of AED therapy is likely to reduce recurrence risk within the first 2 years.[4]

In A.R.'s case, the potential benefits of immediate introduction of AED therapy appear to outweigh potential risks. She experienced complex partial seizures and some were followed by secondarily generalized tonic–clonic seizures. Recurrence of seizure activity is likely to result in physical injury, social embarrassment, and interference with her participation in activities typical of a person her age. If her seizures are not controlled, she faces future limitation of her driving privileges and may face barriers to employment. Although AED therapy is associated with risks, they probably are outweighed by the potential benefits.

CHOICE OF ANTIEPILEPTIC DRUG

CASE 60-1, QUESTION 3: Which AEDs are commonly used for A.R.'s seizure type? Based on the subjective and objective data available, recommend a first-choice AED for A.R. and a plan for initial dosing of this medication.

Many AEDs would be appropriate choices for A.R.'s complex partial seizures that can secondarily generalize (Table 60-3).[34],[50],[51] Some AEDs are not FDA-approved as initial monotherapy. Although valproate is effective for treating both generalized and complex partial seizures,[52] it would not be a good initial choice for this patient owing to the increased risks in a woman of childbearing age (see Women's Issues in Epilepsy section).

Eslicarbazepine, ezogabine, felbamate, gabapentin, lacosamide, lamotrigine, levetiracetam, oxcarbazepine, perampanel, pregabalin, tiagabine, topiramate, and zonisamide are effective for control of partial seizures with or without secondary generalization. Most experience with these drugs was obtained when they were used as adjunctive agents when previous AED therapies were unsuccessful. Initial clinical trials with these medications indicate that several of them may be useful as single agents. Felbamate, lacosamide, lamotrigine, oxcarbazepine, and topiramate have monotherapy indications. Most of the more recently approved medications appear to be safe and are usually well tolerated. The usefulness of felbamate is limited, however, owing to its potential for serious hematologic and hepatic toxicity.

Carbamazepine has several advantages that make it a preferred first-choice agent in the opinion of many clinicians. In comparison with phenytoin, carbamazepine is less sedating and is not associated with dysmorphic effects, such as hirsutism, acne, gingival hyperplasia, and coarsening of facial features. Carbamazepine's pharmacokinetic profile also makes dosage adjustment easier. In A.R.'s case, the lack of cosmetic side effects may be especially significant because she may be taking medication for many years. In addition, reduced sedation may be important with respect to her school performance.

CARBAMAZEPINE THERAPY

Initiation and Dosage

Initiation of treatment with full therapeutic maintenance doses of carbamazepine often causes excessive side effects such as nausea, vomiting, diplopia, and significant sedation. Therefore, carbamazepine therapy should be initiated gradually and patients should be allowed time to acclimate to the effects of the drug. Final dosing requirements are difficult to anticipate in individual patients. A reasonable starting dosage of carbamazepine for A.R. would be 100 mg twice a day; her dosage could be increased by 100 to 200 mg/day every 7 to 14 days. The rapidity of increases will depend on A.R.'s tolerance for the drug and the frequency of her seizures.

Hematologic Toxicity

CASE 60-1, QUESTION 4: Carbamazepine has been associated with hematologic and hepatic toxicities. What is the incidence and significance of these toxicities? How should A.R. be monitored for them?

Aplastic anemia and agranulocytosis have occurred in association with carbamazepine therapy.[53] Several cases have been fatal; however, most cases occurred in older patients treated for trigeminal neuralgia. Many patients were receiving other medications, and occasionally the reports were incomplete; thus, assessment of a causal role for carbamazepine is difficult.[54] Severe blood dyscrasias from carbamazepine seem rare (estimated prevalence <1/50,000) and have predominantly occurred in nonepileptic patients. The lack of severe hematologic toxicity in various published series and clinical trials in patients with epilepsy has been notable.[55],[56]

Leukopenia is relatively common in patients taking carbamazepine. It is usually mild and often reverses despite continued administration of the drug.[55] Total leukocyte counts may fall to less than 4,000 cells/μL in some patients, but differentials and platelet and erythrocyte counts remain normal. Symptoms (e.g., fever, sore throat) that might suggest early stages of agranulocytosis do not occur. Carbamazepine-associated hematologic disorders are unrelated to drug dosage; thus, these reactions appear to be idiosyncratic.

Routine Hematologic Testing

Laboratory monitoring of A.R.'s hematologic status is recommended during carbamazepine therapy. The likelihood of early detection of aplastic anemia or agranulocytosis through frequent blood counts is low, however, and such monitoring is costly.[55],[57] Because hematologic toxicity from carbamazepine primarily occurs early in therapy, a CBC should be obtained before therapy and at monthly intervals during the first 2 to 3 months of therapy; thereafter, a yearly or every-other-year CBC, white blood cell count with differential, and platelet count should be sufficient.

Hepatotoxicity

Carbamazepine-related liver damage is extremely rare despite its being frequently mentioned as a potential problem and strong warnings in the package insert.[58],[59] Hepatic adverse reactions are believed to be idiosyncratic or immunologically based. Aggressive laboratory monitoring of liver function tests (LFTs) probably is unnecessary.[57] Alkaline phosphatase and γ-glutamyl-transferase concentrations often are elevated in patients taking carbamazepine (and other AEDs). This is believed to result from hepatic enzyme induction and is not necessarily evidence for hepatic disease.[60]

In summary, hepatic and hematologic toxicities of carbamazepine are rare. Although potentially serious, they are best monitored on clinical grounds rather than by ongoing, intensive laboratory testing. Patients, families, or caregivers should be aware that the appearance of unusual symptoms (e.g., jaundice, abdominal pain, excessive bruising and bleeding, or sudden onset of severe sore throat with fever) should be reported to a health care professional. Baseline (pretreatment) determination of A.R.'s hepatic and hematologic status, possibly with monthly follow-up testing for 2 to 3 months, probably will be sufficient.[56,57] Thereafter, a CBC and a liver function battery should probably be evaluated only every 1 to 2 years, unless signs or symptoms of hepatic or hematologic disorders are observed.

Pharmacokinetics and Autoinduction of Metabolism

CASE 60-1, QUESTION 5: For the subsequent 6 weeks, A.R.'s carbamazepine dosage was gradually increased to 400 mg twice daily (BID) (20 mg/kg/day). Until the last dose increase, she had been experiencing one or two complex partial seizures weekly; she had experienced only one generalized tonic–clonic seizure since her hospitalization. One week after the increase to 20 mg/kg/day, her serum carbamazepine concentration was 9 mcg/mL just before her first dose of the day. No seizures occurred for 4 weeks, and she tolerated the medication well. Subsequent to the 4-week seizure-free period, she again began experiencing one seizure weekly. What factor(s) might be responsible for this reversal of seizure control?

Several factors may account for this change. It is important always to consider the possibility of poor medication adherence when clinical response changes unexpectedly. This should be investigated, and A.R. and her family should be educated regarding the importance of regular medication intake.

The observed changes in A.R.'s seizure control may also be due to unique features of carbamazepine pharmacokinetics. Carbamazepine is a potent inducer of hepatic cytochrome P-450 (CYP3A4). The drug is also a substrate for this enzyme. As a result, carbamazepine not only stimulates the metabolism of other CYP3A4 substrates but also induces its own metabolism by autoinduction. Carbamazepine's half-life after single acute doses is approximately 35 hours; with chronic dosing, its half-life decreases to 15 to 25 hours. This increase in clearance necessitates increased carbamazepine doses, increased frequency of administration, or both. Autoinduction of carbamazepine metabolism appears to be related to dose and serum concentration. Approximately 1 month may be required for the autoinduction process to reach completion after each increase in carbamazepine dose.[61]

Assuming that adherence was not the main problem, A.R.'s carbamazepine dose should be increased. The drug's pharmacokinetics are generally linear with respect to acute dosage changes.[62] A 50% increase in dosage to 1,200 mg/day should re-establish seizure control. Depending on A.R.'s clinical status, further increases in dosage may be necessary.

Bioequivalence of Generic Dosage

CASE 60-1, QUESTION 6: A.R.'s dosage was increased to 600 mg BID. Four weeks later, she was still experiencing approximately one complex partial seizure weekly. A repeat trough serum carbamazepine concentration was 6.5 mcg/mL. On questioning, A.R. denied missing doses of medication, and a tablet count confirmed apparently accurate drug intake. A.R. relates that she experiences some mild nausea after her doses, but she has not vomited. It is noted that her pharmacist has begun substituting a generic carbamazepine tablets for the Tegretol that was previously dispensed. What role, if any, might this change in carbamazepine formulation have played in the failure of A.R.'s serum concentrations to increase as expected? What other factors might be considered in explaining this situation?

Several manufacturers market generic carbamazepine tablets. Bioavailability data supplied by the manufacturers are based on single-dose or short multiple-dose studies in healthy subjects. Therefore, it is impossible to completely predict the results of a change from Tegretol to generic carbamazepine for maintenance therapy in an individual patient.[63] Because of variations in amount of drug available from different products, some patients with epilepsy (aka "generic-brittle") cannot tolerate changes in formulations between brand and generic, generic and generic, or generic and brand.[64] Changes in seizure control from too little drug or toxicity from too much drug have been reported with changes between formulations for several AEDs. On the other hand, two recent in-depth bioequivalence studies have found no evidence to support any pharmacokinetic differences between brand and generic products of lamotrigine in patients with epilepsy.[65],[66]

Bioavailability data suggest that the generic carbamazepine preparations currently on the market may be substituted for Tegretol with little need for dosage adjustment. Nonetheless, in A.R.'s case, substitution of generic carbamazepine may be a possible cause for the loss of seizure control. Readjustment of her dose to gain seizure control and consistent use of one manufacturer's product (either brand or generic) might alleviate this problem. Three extended-release forms of carbamazepine (Tegretol XR, Carbatrol, and Equetro) are available and may provide an alternative for A.R. These formulations allow more reliable absorption of drug when administered on a twice-daily dosing schedule. Many patients can better tolerate carbamazepine when these forms are used because large fluctuations in plasma concentrations are avoided. Use of Tegretol XR to avoid 3-times-daily or 4-times-daily dosing schedules has been shown to increase adherence for many patients.[67] It is important to counsel patients on the fact that the empty Oros tablet shell from the Tegretol XR dose does not dissolve as it passes through the gastrointestinal (GI) tract, and it may be visible in the stool. Patients need to understand that the carbamazepine has been absorbed, and that this is an empty shell. Tegretol XR tablets lose their extended-release properties when broken or crushed; Carbatrol beads may be emptied onto food or administered via feeding tube.[68] Equetro is not FDA-approved for epilepsy, it is indicated for the treatment of acute manic and mixed episodes associated with bipolar I disorder.

In conclusion, it may be impossible to identify a single cause for the unexpected change in A.R.'s seizure control. Common reasons for loss of seizure control include sleep deprivation, increased stress, acute illness, and/or medication nonadherence.

TREATMENT FAILURE AND ALTERNATIVE ANTIEPILEPTIC DRUGS

CASE 60-2

QUESTION 1: R.H., a 19-year-old, 64-kg young woman, has experienced simple partial seizures, complex partial seizures, and secondarily generalized tonic–clonic seizures for the past 2 years. She could not tolerate treatment with phenytoin (severe gingival hyperplasia and mental "dullness") or valproate (hair loss, tremor, and a weight gain of 8 kg). In addition, neither phenytoin nor valproate was dramatically effective in reducing her seizures. She currently receives carbamazepine 600 mg 3 times daily (TID). For the past 3 months, while being treated with carbamazepine, she has had approximately five simple partial seizures, three complex partial seizures, and one generalized tonic–clonic seizure. This represents an approximate 30% reduction in her frequency of seizures. She tolerates her present dose of carbamazepine but has experienced significant drowsiness, incoordination, and mental confusion at higher doses. What are possible therapeutic options for R.H.? Evaluate the newer AEDs and their possible usefulness for R.H.

R.H. is exhibiting a partial response to maximally tolerated doses of carbamazepine. An alteration in her current AED regimen is indicated. She has not tolerated other AEDs because of side effects. Although valproate is effective for control of partial seizures, it is not considered an alternative in a woman of childbearing age.

R.H.'s CNS side effects (e.g., persistent drowsiness) with other AEDs would make many clinicians reluctant to consider medications such as phenobarbital or primidone as either alternatives or adjunctive agents to her current carbamazepine regimen. Use of one of the newer AEDs as adjunctive medication may be of value for R.H.

New AEDs marketed in the United States since 1993 for maintenance treatment of epilepsy include the following: eslicarbazepine, ezogabine, felbamate, gabapentin, lacosamide, lamotrigine, levetiracetam, oxcarbazepine, perampanel, pregabalin, tiagabine, topiramate, and zonisamide (Table 60-6). Clinical trials for new AEDs are most often carried out in patients with partial seizures refractory to standard AEDs.

Most of these newer or “second-generation” AEDs were initially FDA-approved as “add-on” or adjunctive treatment in patients with partial seizures with or without secondary generalization. Also, consensus is that some of these AEDs may be effective as broad-spectrum agents; for example, lamotrigine appears to be a useful treatment in absence seizures.

Side Effects

Common side effects for the newer AEDs are described in Table 60-6. Most of them are less sedating than older medications such as phenobarbital or phenytoin. The most common side effects seen in the clinical trials with eslicarbazepine were ataxia, blurred and double vision, dizziness, fatigue, headache, nausea, somnolence, tremor, vertigo, and vomiting.[69]

Gabapentin and tiagabine have not been associated with serious side effects; gabapentin can cause weight gain[70] and tiagabine can cause nonspecific dizziness relatively frequently.[71]

Common adverse effects associated with lacosamide include dizziness, headache, diplopia, and nausea. Gradual escalation to the desired dose reduces the adverse event risk.

The most serious adverse effect associated with lamotrigine is skin rash. Rashes occur in approximately 10% of treated patients, usually in the first 8 weeks.[72] Rashes leading to hospitalization occurred in 1 of 300 adults and 1 of 100 children. Widespread, maculopapular rashes usually appear and may progress to erythema multiforme or toxic epidermal necrolysis. Lamotrigine-related rashes may resolve rapidly when lamotrigine is discontinued. Coadministration of valproate with lamotrigine may increase the likelihood of dermatologic reactions; it is partly for this reason that more conservative dosage titration and lower maintenance doses of lamotrigine are recommended for patients receiving concomitant valproate. Higher starting doses and more rapid dose escalation than those recommended by the manufacturer also increase the risk of skin rash.

Levetiracetam is generally well tolerated, with the most common adverse events in clinical trials being asthenia, vertigo, flu syndrome, headache, rhinitis, and somnolence. The most serious adverse effects are behavioral and are more common in patients with a history of behavioral problems.[73] Levetiracetam should be used with caution in patients with a history of suicidal ideations.

Oxcarbazepine, a keto derivative of carbamazepine, is essentially a prodrug for the monohydroxy active metabolite.[74] Oxcarbazepine probably causes less frequent, less severe adverse effects compared with carbamazepine, with the exception of hyponatremia. Hyponatremia is more common with oxcarbazepine than with carbamazepine. Baseline and periodic serum sodium monitoring is indicated during oxcarbazepine therapy. The most commonly reported side effects of oxcarbazepine in clinical trials include ataxia, dizziness, fatigue, nausea, somnolence, and diplopia.

Adverse effects of pregabalin are dose dependent and usually occur within the first

2 weeks of treatment.[75] Somnolence, dizziness, and ataxia are most common. Pregabalin also appears to be associated with a dose-related weight gain.

Topiramate can cause cognitive disturbances, lethargy, and impaired mental concentration when given in large daily doses (especially in combination with other AEDs) or when the dosage is titrated too aggressively.[76] Topiramate has caused nephrolithiasis in approximately 1.5% of treated patients. This adverse effect is believed to be related to inhibition of carbonic anhydrase by topiramate, with resulting increased urinary pH and decreased citrate excretion. Topiramate can also cause acute, secondary angle-closure glaucoma, which presents within the first month of therapy. Topiramate is associated with weight loss.

Zonisamide is a sulfonamide derivative and thus is contraindicated in patients allergic to sulfonamides.[77] The most commonly reported adverse events include ataxia, somnolence, agitation, and anorexia. Kidney stones have developed in 3% to 4% of patients, some of whom had a family history of nephrolithiasis.

Pharmacokinetics

The newer AEDs have somewhat different pharmacokinetic profiles from those of older agents. They also differ in their tendency to interact with other AEDs. Gabapentin is excreted entirely by the kidneys as unchanged drug and is not significantly bound to plasma protein. Gabapentin has a relatively short half-life and should be administered 3 times daily.[78]

Lacosamide is excreted mostly by the kidneys. Dosage reductions are warranted for patients with renal impairment (creatinine clearance <30 mL/minute). It is less than 15% bound to plasma protein, has a 12- to 13-hour half-life, and is administered twice daily.[79]

Lamotrigine is primarily eliminated by hepatic glucuronidation and excretion of metabolites in the urine. Other AEDs, such as carbamazepine and phenytoin, induce the hepatic metabolism of lamotrigine. When lamotrigine is coadministered with enzyme-inducing drugs, its half-life decreases from approximately 24 to 15 hours. Valproate inhibits lamotrigine metabolism, causing increases in half-life and serum concentrations.[80],[81] Patients treated with both lamotrigine and carbamazepine may experience more nausea, drowsiness, and ataxia. It appears likely that this interaction represents a pharmacodynamic interaction between lamotrigine and carbamazepine.[82]

Levetiracetam has a short half-life and is eliminated primarily by renal mechanisms. Dosage reductions are warranted for patients with renal impairment (creatinine clearance <80 mL/minute). The drug has a low potential for interactions with other drugs.[83]

Both eslicarbazepine acetate and oxcarbazepine are prodrugs. They cause less hepatic enzyme induction than carbamazepine and may therefore be less likely to interact with other medications. Both, however, increase the metabolism of oral contraceptive hormones.[84],[85] Because eslicarbazepine and oxcarbazepine have similar mechanisms of action to that of carbamazepine, it is unlikely that either would offer significant benefits to R.H. because she has not responded to maximal tolerated doses of carbamazepine.[69],[74]

Pregabalin is excreted entirely by the kidneys as unchanged drug and is not significantly bound to serum proteins. Unlike gabapentin, which requires more frequent dosing, pregabalin can be administered 2 or 3 times daily.[75]

Tiagabine has a relatively short half-life (4–7 hours). It should be administered at least twice daily.[71] Concurrently administered enzyme-inducing AEDs may reduce the half-life of tiagabine to 2 to 3 hours and necessitate use of larger daily doses and, possibly, shorter dosing intervals. Tiagabine is highly protein-bound (96%), and it is displaced from protein-binding sites by valproate, salicylate, and naproxen. The clinical significance of these protein-binding interactions is unknown.

Topiramate has a half-life of approximately 20 hours, which allows twice-daily administration. It is only partially excreted by hepatic metabolism; approximately 70% of the drug is excreted unchanged by the kidneys. Topiramate is minimally protein-bound (~10%–15%). When topiramate is coadministered with enzyme-inducing agents, topiramate clearance is increased. This interaction may necessitate titration to somewhat higher doses when topiramate is used with enzyme-inducing drugs.

Table 60-6

Drugs Used for the Treatment of Partial and Generalized Tonic–Clonic Seizures

AED	Regimen	Adverse Effects	Comments
Carbamazepine (Tegretol, Tegretol XR, Carbatrol, Equetro)	Initial 200 mg BID (adults) or 100 mg BID (children) and weekly until therapeutic response or target serum concentrations. Usual maintenance doses 7–15 mg/kg/day in adults; 10–40 mg/kg/day in children	Sedation, visual disturbance may limit dosage. Severe blood dyscrasias extremely rare. Mild leukopenia more common. Laboratory monitoring of little value. Asian patients positive for HLA-B*1502 are at 10-fold higher risk for Stevens–Johnson syndrome/toxic epidermal necrolysis. Hepatotoxicity rare. May cause hyponatremia. Long-term use may cause osteomalacia	Usually little sedation and minimal interference with cognitive function or behavior. Preferred by most for partial or secondarily generalized seizures. Extended-release products may allow less frequent dosing with fewer peak serum concentration-related side effects. These products may also facilitate adherence
Phenytoin (Dilantin, Phenytek)	Initiate at maintenance dose of 4–5 mg/kg/day (300–400 mg/day). Titrate on basis of	Nystagmus, ataxia, sedation may limit dosage. Gum hyperplasia, hirsutism	Clearance and half-life change with dose. Small ↑ in dose (30-mg capsule)

Fosphenytoin (Cerebyx)	clinical response and target serum concentration. 3–4 weeks between dose ↑ recommended because of potentially slow accumulation	common. Long-term use may cause osteomalacia. Peripheral neuropathy, hypersensitivity with liver damage rare. Possible increased risk of Stevens–Johnson syndrome/toxic epidermal necrolysis in Asian patients positive for HLA-B*1502	recommended as plasma concentrations exceed 7–10 mcg/mL. Cautious use of suspension; dose measurement and potential mixing difficulties. IM administration not recommended. Potential precipitation in IV solutions. Fosphenytoin (Cerebyx) recommended for IM and IV use due to faster administration rate, admixture compatibility, and lower rate of injection site complications
Valproate (Depakene, Depakote, Depakote-ER, Depacon)	See Table 60-7	–	–
Phenobarbital	Initial 1 mg/kg/day; titrate to therapeutic response. 2–3 weeks between dose ↑	Sedation (chronic), behavior disturbances common, especially in children. Possibly impairs learning and intellectual performance. Long-term use may cause osteomalacia	Considered outmoded for AED therapy in most patients; adverse effects outweigh benefits. IV use for refractory status epilepticus
Pregabalin (Lyrica)	Initial 50 mg BID then titrate to therapeutic response with maximal daily dose at 600 mg/day in divided doses (BID or TID)	Potential side effects include dizziness, blurred vision and weight gain	No significant interactions with other AEDs. Can be useful for patients with concomitant pain disorders
Gabapentin (Neurontin)	Initial 300 mg/day with titration to 900–1,800 mg/day for 1–2 weeks. Doses of 2,400 mg/day and higher have been well tolerated. Owing to short half-life, TID or QID dosing recommended	Sedation, dizziness, and ataxia relatively common with initiation of therapy. Gabapentin therapy usually not associated with prominent side effects. Commonly associated with weight gain	Excreted unchanged by kidneys. No significant drug–drug interactions. Absorption dose dependent; fraction absorbed ↓ as size of individual dose ↑
Lamotrigine (Lamictal)	When added to enzyme inducers alone: Initiate at 50 mg daily HS or 50 mg BID. Daily dose can be ↑ by 50–100 mg every 7–14 days. Usual maintenance doses of 400–500 mg/day. BID dosing may be necessary with enzyme inducer cotherapy. When added to valproate alone: Initiate at 25 mg QOD HS. Daily dose can be ↑ by 25 mg	Dizziness, diplopia, sedation, ataxia, and blurred vision can be common with initiation of therapy; limit speed of titration. Incidence of serious rash ranges from 0.8–8.0 per 1,000	Significant ↑ in clearance of lamotrigine when coadministered with enzyme inducers. Significant ↓ in clearance when coadministered with valproate. Slow, gradual titration of dose may reduce risk of skin rash. Estrogen increases clearance

	every 14 days. Usual maintenance doses of 100–200 mg/day. For patients not taking valproate or an enzyme inducer: Initiate at 25 mg QD HS. Daily dose can be ↑ by 25 mg every 14 days. Usual daily doses of 225–375 mg/day		

Tiagabine (Gabitril)	Initial 4 mg/day. ↑ by 4 mg/day at 7 days. Then ↑ daily dose by 4–8 mg every week. Maximal recommended dose of 32 mg/day in adolescents or 56 mg/day in adults. BID to QID dosing recommended	Drowsiness, nervousness, difficulty with concentration or attention, tremor. Nonspecific dizziness described by some patients	Increased clearance when given with enzyme inducers. TID or QID doses probably needed. Potential for protein-binding displacement interactions with other highly protein-bound drugs (e.g., valproate). Significance of protein-binding displacement not known. Substrate for CYP3A4
Topiramate (Topamax, Trokendi, Qudexy)	Initial 50 mg HS. ↑ daily dose by 50 mg every 7 days. 200–400 mg/day recommended as target dosage range. Larger daily doses associated with increased CNS side effects. BID dosing recommended	Sedation, dizziness, difficulty concentrating, confusion. May be dose related. Possible weight loss. Weak CA inhibitor; may cause or predispose to kidney stones; CA inhibition also possibly related to paresthesias in up to 15%. Risk of hypohidrosis and hyperthermia especially in children. Rarely associated with angle-closure glaucoma	Approximately 70% renal elimination. Phenytoin and carbamazepine may reduce topiramate plasma concentrations and potentially increase dosage requirements. Topiramate may cause small ↑ in phenytoin plasma concentration. Advise patients to drink plenty of fluids. May affect oral contraceptives above 200 mg/day
Levetiracetam (Keppra, Keppra-XR, Spritam)	Initial 250–500 mg BID. ↑ by 500–1,000 mg/day every 2 weeks. Usual maximal dose is 3,000 mg/day. Doses up to 4,000 mg/day have been used. BID dosing recommended	Somnolence, dizziness, asthenia are commonly reported. Behavioral symptoms (agitation, emotional lability, hostility, depression, and depersonalization) reported	No hepatic (CYP450 or UGT) metabolism. 66% excreted unchanged in urine. Less than 10% protein bound. No significant drug interactions reported
Lacosamide (Vimpat)	Initiate at 50 mg BID. Increase weekly by 100 mg/day. Target doses of 200–400 mg/day.	Dizziness, ataxia, diplopia, headache, nausea. May slow cardiac conduction.	Currently only indicated for treatment of partial seizures in adults. IV form

	Maximum recommended dose is 400 mg/day	Caution is advised in patients with second-degree AV block. Syncope has been reported	available; currently only approved for short-term replacement of oral therapy. Little evidence of significant risk of drug–drug interactions. Some hepatic metabolism by CYP2C19; significant renal elimination
Oxcarbazepine (Trileptal, Oxtellar)	Monotherapy: Initial 300 mg BID. ↑ weekly up to 1,200 mg/day. Can increase to 2,400 mg/day.Adjunctive therapy: Initial 300 mg BID. ↑ weekly up to 1,200 mg/day	Dizziness, somnolence, diplopia, nausea, and ataxia are commonly reported. May cause hyponatremia; most cases asymptomatic, more common in elderly. A 25% cross-sensitivity for skin rash reported between oxcarbazepine and carbamazepine	Parent is a prodrug; the MHD is the active component. Readily converted to MHD via omnipresent cytosolic enzymes. Lacks autoinduction properties. In doses >1,200 mg/day, may affect oral contraceptives
Zonisamide (Zonegran)	Initial 100 mg daily. ↑ by 100 mg/day every 2 weeks. Usual maintenance doses of 200–400 mg/day; maximum 600 mg/day	Somnolence, nausea, ataxia, dizziness, headache, and anorexia are common. Weight loss and nephrolithiasis reported. Serious skin eruptions, oligohidrosis, and hyperthermia have also occurred	Broad spectrum, long half-life. 35% of dose is excreted unchanged in the urine. Also a substrate of CYP3A4; enzyme induction may increase clearance. Advise patients to drink plenty of fluids
Ezogabine (Potiga)	Initial 100 mg TID. ↑ by 150 mg/day every week. 600–1,200 mg/day recommended as target dosage range. TID dosing recommended	Dizziness, fatigue and somnolence are commonly reported. Urinary retention, confusion, and hallucinations. Reddish-orange urine discoloration is benign. Prolongs QT interval. Retinal abnormalities and potential vision loss	Phenytoin and carbamazepine reduce ezogabine exposure by 30%–35%. Higher doses may be needed. Monitor vision and eye examination

---

Perampanel (Fycompa)	Initial 2 mg once daily HS (not on enzyme-inducing AEDs) or 4 mg once daily HS (on enzyme-inducing AEDs). ↑ by 2 mg/day every week. 4–12 mg/day recommended as target dosage range. Once-daily dosing HS recommended	Dizziness, gait disturbance, somnolence and fatigue are commonly reported. Risk of falls in elderly patients. Aggression, hostility, irritability, anger and homicidal ideation. May be worsened by alcohol	Avoidance of alcohol is recommended. Enzyme-inducing AEDs reduce perampanel exposure by 50%–67%. Higher doses may be needed. Perampanel 12 mg/day may reduce effectiveness of hormonal

			contraceptives containing levonorgestrel
Eslicarbazepine (Aptiom)	Initial 400 mg once daily. ↑ by 400 mg/day after one week. Maximum recommended dose is 1,200 mg/day. Once-daily dosing recommended	Dizziness, somnolence, nausea, and headache	Enzyme-inducing AEDs reduce eslicarbazepine exposure. Higher doses may be needed. May reduce effectiveness of hormonal contraceptives

AED, antiepileptic drugs; AV, atrioventricular; BID, twice daily; CA, carbonic anhydrase; CNS, central nervous system; CYP, cytochrome P-450; GI, gastrointestinal; HS, at bedtime; IM, intramuscular; IV, intravenous; MHD, monohydroxy derivative; PE, phenytoin sodium equivalent; QID, four times daily; QOD, every other day; SIADH, syndrome of inappropriate antidiuretic hormone secretion; TID, three times daily; UGT, uridine diphosphate glucuronosyltransferase; VPA, valproic acid.

Zonisamide has a long half-life and low protein binding. It is eliminated by both hepatic metabolism and renal excretion. The average half-life of zonisamide is 63 hours, but there is wide interpatient variation. Serum levels of zonisamide are reduced by enzyme-inducing AEDs but clinical consequences of pharmacokinetic interactions with zonisamide are rare.[77]

On the basis of efficacy and side effect characteristics, gabapentin, lacosamide, lamotrigine, levetiracetam, pregabalin, tiagabine, topiramate, or zonisamide could be considered for use as adjunctive therapy for R.H. In young, active patients such as R.H., sedation might prove to be a problem; however, it is not clear that any of these drugs predictably causes more initial or long-term sedation. The short half-lives of gabapentin and tiagabine and the associated need for R.H. to take several doses during the day might decrease her adherence. Therefore, lacosamide, lamotrigine, levetiracetam, pregabalin, topiramate, or zonisamide would be reasonable choices on the basis of convenience. Because the patient is not tolerating carbamazepine, it does not make sense to switch to either eslicarbazepine or oxcarbazepine.

The reason that ezogabine, felbamate, and perampanel were not discussed in the side effects and pharmacokinetics sections above is that these authors do not believe they are good options for R.H. at this point. Ezogabine and perampanel are very new to the market at the time of this writing and both have FDA boxed warnings (vision problems and behavioral reactions, respectively). Felbamate's usefulness is seriously limited by its association with aplastic anemia and hepatic failure.

Potential Therapies

Other AEDs that may become available in the near future include brivaracetam, ganaxolone, and huperzine A.[86] These drugs may become useful as alternatives or adjuncts to established and newer medications in the future.

With advancing technology and knowledge about genes and brain networks, future treatment strategies should move from controlling symptoms of epilepsy with AEDs to prevention and cure. For AED-resistant epilepsy, much research is examining the role of multidrug transporters (e.g., P-glycoprotein) at the blood–brain barrier. These proteins may act as a defense mechanism by limiting the accumulation of AED in the brain.[87] Although it has not yet had much of an impact on the clinical care of patients with epilepsy, pharmacogenetics of AED therapy is continually advancing.[88]

LAMOTRIGINE THERAPY

Initiation and Dosage Titration

CASE 60-2, QUESTION 2: R.H. is to be started on lamotrigine as adjunctive therapy to her carbamazepine. Outline a treatment plan for initiating and monitoring therapy for R.H. What should R.H. and her family be told about this medication and how to use it?

Lamotrigine therapy should be initiated in R.H. with a slow upward dosage titration to minimize early sedative effects and reduce the likelihood of skin rash. An initial dosage of 50 mg/day given at bedtime is recommended; the daily dose can be increased by 50 mg every 1 to 2 weeks. Because R.H. is currently receiving carbamazepine, induction of liver enzymes is likely to increase her dosage requirements for lamotrigine and allow a less conservative dosage titration. A twice-daily schedule is recommended for maintenance therapy. Usual maintenance dosages of lamotrigine are approximately 300 to 500 mg/day. A patient's ability to tolerate this medication ultimately determines dosage limitations. Onset of side effects (e.g., nausea, diplopia, ataxia, and dizziness) may prevent further dosage increases.

R.H. should be told that she may feel drowsy and possibly experience headache and upset stomach, but that these side effects usually disappear with ongoing therapy. She should contact her physician or other health care professional if severe side effects occur that make it difficult to take the medication; this is especially important if she exhibits a rash.

Side Effects and Possible Interaction with Carbamazepine

CASE 60-2, QUESTION 3: Two days after her dosage of lamotrigine was increased to 300 mg/day (12 weeks after beginning therapy), R.H. noticed that her vision was blurring; she also complained of feeling dizzy and having difficulty maintaining her balance. Previously, she had experienced only mild, occasional nausea. She had continued to experience seizures at approximately the same frequency she had before the initiation of lamotrigine. Her physician had encouraged her to continue taking the medication and explained that it would take time to increase the dose to possibly effective levels. Her current carbamazepine serum concentration is essentially unchanged when compared with when she was taking it in monotherapy. Do these new side effects represent treatment failure with lamotrigine? If not, how might these new side effects be managed?

R.H.'s side effects may limit further dosage increases. Her current side effects might represent carbamazepine intoxication, lamotrigine side effects, or an interaction between these two medications. Because R.H. tolerated the same carbamazepine dose previously, carbamazepine "intoxication" seems a less likely cause. Assessing the role of lamotrigine as the only cause is difficult. Obtaining a lamotrigine serum concentration to aid in assessing her adverse effects is not likely to be helpful. A usual "therapeutic range" for lamotrigine serum concentrations has not been established. Clinical studies have failed to demonstrate a significant correlation between lamotrigine serum concentrations and either therapeutic or adverse responses.[89],[90] Her symptoms may also be related to an apparent pharmacodynamic interaction between lamotrigine and carbamazepine.[82] The effects experienced by some patients taking both drugs may be relieved by reducing the carbamazepine dosage.

LEVETIRACETAM THERAPY

Initiation and Dosage Titration

CASE 60-2, QUESTION 4: R.H.'s carbamazepine dosage was reduced from 1,800 mg/day to 1,400 mg/day. After 5 days, her side effects persisted and her seizure frequency appeared to be increasing. The clinician decides to abandon lamotrigine therapy and institute treatment with levetiracetam. Recommend a plan for initiating R.H.'s levetiracetam treatment.

R.H. previously tolerated and had a better therapeutic response to a higher carbamazepine dose. Therefore, the dosage of carbamazepine should be returned to 1,800 mg/day before levetiracetam therapy is initiated. Little specific information is available to help determine how lamotrigine can be safely discontinued. As a general rule, rapid discontinuation of AEDs is not recommended in other than emergency situations. Therefore, immediate reduction of R.H.'s lamotrigine dosage to 200 mg/day would seem reasonable. This dosage could then be reduced by 50 to 100 mg every week until lamotrigine is discontinued.

Levetiracetam treatment should be instituted immediately for R.H. because of her continuing seizures. Levetiracetam does not interact with other AEDs. Therefore, discontinuing lamotrigine during initiation of levetiracetam should not create difficulties in assessing R.H.'s response. Levetiracetam should be initiated at a dosage of 250 to 500 mg 2 times daily.[83] Although the manufacturer recommends initiating treatment at 500 mg twice daily, patients may better tolerate lower initial doses and more gradual titration. R.H.'s daily levetiracetam dose can be increased by 500 to 1,000 mg every 2 or 3 weeks, according to her tolerance of side effects and her change in seizure frequency. Although the drug reaches steady state quickly, allowing at least 2 weeks for observation before dosage increases may improve patient tolerability and allow for a more thorough evaluation of therapeutic response. At present, the relationship between serum concentrations of levetiracetam and therapeutic response or symptoms of intoxication is not well defined. Therefore, R.H.'s dose should be titrated to the maximal tolerated amount required to control her seizures. In controlled trials, no clear benefits were apparent at doses greater than 3,000 mg/day.

Patient Education

R.H. should be informed that with levetiracetam she may experience side effects similar to those she had with lamotrigine. R.H.'s mood should be assessed at each visit. Much reassurance and encouragement may need to be given along with this information to help ensure that R.H. adheres to her treatment regimen. Many patients become discouraged when multiple trials of medication are necessary and side effects are prominent. They may express feelings of being "guinea pigs" and may become uncooperative with the therapeutic plan. Given that RH's seizures are still not well controlled, driving restrictions that were likely put into place earlier should be continued. RH should be counseled not to drive until she is seizure-free and her driving privileges have been reinstated according to applicable state law. This restriction can be very hard for some patients to accept because it can significantly decrease their independence.

PHENYTOIN THERAPY

Initiation and Dosage

CASE 60-3

QUESTION 1: J.N., an 18-year-old, 88-kg male college student, was diagnosed with epilepsy. He experiences generalized tonic–clonic seizures that last 2 minutes approximately 3 times monthly. J.N. describes a "churning" feeling in his abdomen before his seizures; this is followed by involuntary right-sided jerking of his upper extremities. An EEG showed diffuse slowing with focal epileptiform discharges in the left temporal area; it was interpreted as abnormal. No correctable cause for his seizure disorder was identified despite a thorough workup. He has no other medical conditions and takes no routine medications. He was treated initially with carbamazepine up to 600 mg/day. He could not tolerate the medication because of nausea and diplopia despite relatively low doses. J.N.'s physician has elected to implement a therapeutic trial of phenytoin. Recommend an initial dosage. What information should be provided to J.N. about his new medication?

Selecting a nontoxic, therapeutic dose of any AED is difficult without having information about the drug's disposition in the individual patient (i.e., prior dosages and clinical response). Although "average" dosages and resulting serum concentrations for phenytoin often are quoted, interpatient variability is significant. An initial phenytoin dosage of 400 mg/day (approximately 4.5 mg/kg/day) would be appropriate for J.N. In most patients, phenytoin therapy is initiated at or near the anticipated maintenance dose (e.g., 300 or 400 mg daily in J.N.). If tolerability problems arise, J.N.'s phenytoin dose could be reduced to 200 mg daily (or 100 mg every 12 hours) and increased by 100 mg/day at weekly intervals until 400 mg/day is reached. Recently, there has been significant interest in using patient-specific genetic information to more accurately dose certain drugs, including phenytoin, with the goals of achieving a therapeutic effect quickly and avoiding dose-related toxicity. Although certain CYP2C9 homozygous allele variants have been shown to confer "slow-metabolizer" status on patients treated with phenytoin,[91] CYP2C9 genotyping of patients is not presently a part of routine clinical practice.

Patient Education

In addition to the name and strength of the medication and instructions for when and how it should be taken, J.N. should be informed that he may experience initial mild sedation from phenytoin. He should be cautioned that symptoms such as blurred or double vision, dysarthria, dizziness, or staggering may indicate that his dosage is too high; he should be instructed to notify his physician, pharmacist, or other health care professional

---

of these symptoms. It is also a good idea to inform patients, at the beginning of therapy, that adjustments of medication dosage may be necessary before the regimen is stabilized. While RH is at relatively low risk for osteomalacia given his age and gender, he should be informed that long-term use of phenytoin (as well as other AEDs; see Table 60-6) is associated with an increased risk of bone mineral loss and that this adverse effect warrants monitoring periodically.

Accumulation Pharmacokinetics

CASE 60-3, QUESTION 2: What are the characteristics of phenytoin accumulation pharmacokinetics?

Phenytoin exhibits dose-dependent (Michaelis–Menten or capacity-limited) pharmacokinetics; therefore, the usual pharmacokinetic concepts of "clearance" and "half-life" are meaningless. The apparent half-life of phenytoin changes with the dose and serum concentration. Thus, the time required to reach a new steady state after dose alteration is difficult to predict because it depends on the dose itself and the patient's pharmacokinetic parameters, V_{max} and K_m.[92] V_{max} is a kinetic constant representing the maximal rate of phenytoin elimination from the body. K_m is the Michaelis constant, the serum concentration at which the rate of elimination is 50% of V_{max}. Values for these parameters vary widely among patients; as a result, patterns of phenytoin accumulation and the time required to achieve steady state also vary.

Many clinicians assume that phenytoin's apparent half-life is approximately 24 hours, and they wait 5 to 7 days before assessing the patient's clinical response and measuring serum phenytoin concentrations. Both clinical studies[93] and model simulations[94] using observed values for K_m and V_{max} have been used to estimate time required for serum concentrations of phenytoin to reach steady state. Up to 30 days may be needed for this to occur either with doses sufficient to produce steady state serum concentrations of 10 to 15 mcg/mL or with doses of 4 mg/kg/day.[92,95] Occasionally, such a dose may exceed a patient's V_{max}; the result is extremely high serum phenytoin concentrations, with probable intoxication. It is important not to assume that steady state has been reached unless widely spaced, serial serum concentrations indicate that accumulation has ceased. Alterations in phenytoin dosage before steady state has been reached can result in significant fluctuations in serum concentrations and the patient's clinical status. Such situations occur frequently and result in unnecessary confusion and expense. As always, serum concentrations in J.N. must be interpreted in the context of his clinical response.

Phenytoin Intoxication

CASE 60-3, QUESTION 3: J.N. was started on phenytoin and is now taking 200 mg every 12 hours. One week after achieving this dose, mild lateral gaze nystagmus was noted, but J.N. had no subjective complaints and was seizure-free. After 3 weeks, J.N. complained of double vision and feeling "drunk" and "unsteady." Significant nystagmus was present. How should J.N.'s phenytoin dosage be altered?

J.N.'s signs and symptoms indicate phenytoin intoxication. Dosage reduction is indicated. Reducing J.N.'s dosage to 360 mg/day (accomplished using both 100-mg and 30-mg phenytoin capsules) would be reasonable. A larger reduction may result in a loss of seizure control. Many clinicians also would have J.N. omit one day's dose of phenytoin before beginning the new maintenance dosage. This would accelerate the decline in phenytoin serum levels. After this dosage change, clinical response should be monitored closely. The new maintenance dose may still be excessive, if J.N.'s V_{max} for phenytoin is low. If this were the case, continued accumulation of drug would occur despite the dosage reduction.[92]

Intramuscular (IM) Phenytoin and Fosphenytoin (Phenytoin Prodrug)

CASE 60-4

QUESTION 1: S.D. is a 24-year-old male institutionalized patient with a history of complex partial and secondarily generalized tonic–clonic seizures. Within the past year, his phenytoin formulation was switched from phenytoin sodium capsules to phenytoin suspension because S.D. was suspected of "cheeking" his medicines and not swallowing the capsules. He has had no seizures in the past 3 months on 275 mg/day of phenytoin suspension. S.D. has now been transferred to the acute medical unit after a 2-day history of anorexia, nausea, occasional vomiting, and abdominal pain accompanied by diarrhea. His chart now states "nothing by mouth." IM fosphenytoin, 275 mg (phenytoin sodium equivalents [PEs]) per day, has been ordered. Discuss the use of IM fosphenytoin, and devise a dosage regimen for S.D.

S.D. is a candidate for parenteral administration of his AED. If placement of an IV line for fluid administration is not planned, then IM administration is an acceptable approach to treatment; however, the type of phenytoin product administered will need to be changed. Phenytoin, itself, should not be administered by IM injection. Injectable phenytoin is highly alkaline (pH 12) and extremely irritating to tissue. After IM injection, the drug may precipitate at the injection site because of the change in pH. As a result, phenytoin crystals form a repository or depot from which the drug is slowly absorbed.[96–98] Often injection site discomfort is noted, although severe muscle damage does not seem to occur.[98]

Fosphenytoin, a phosphate ester prodrug of phenytoin, is highly water-soluble. Its solubility allows this preparation to be administered parenterally without the need for solubilization using propylene glycol or the adjustment of pH to nonphysiologic levels. Therefore, fosphenytoin may be administered either IM or IV with less risk of tissue damage and venous irritation than with parenteral administration of phenytoin.[99–101] (See also subsequent discussion of IV administration of phenytoin and fosphenytoin.) After administration, fosphenytoin is rapidly absorbed and converted to phenytoin by phosphatase enzymes. Ultimately, the bioavailability of phenytoin from IM fosphenytoin administration is 100%.

Fosphenytoin is available as a solution containing 50 mg PE/mL. By labeling fosphenytoin this way, no dosing adjustments are necessary when converting from phenytoin sodium to fosphenytoin or vice versa. Although the prescriber ordered 275 mg PE, S.D. may be underdosed. His oral dosage of phenytoin suspension is providing the equivalent of 300 mg/day of sodium phenytoin. Phenytoin suspension and chewable tablets contain free acid, whereas capsules contain sodium phenytoin. Therefore, phenytoin capsule products contain only 92% of the labeled content as phenytoin acid (i.e., a 100-mg sodium phenytoin capsule contains only 92 mg of phenytoin acid). He should receive a 300-mg dose of fosphenytoin daily to fully replace his current dosage of phenytoin suspension.[101]

Assuming that S.D. will be given 300 mg PE of fosphenytoin daily, he will require a total of 6 mL of this injection given IM. This medication is well tolerated when given IM, and S.D.'s full daily dose can be given in a single injection without causing excessive discomfort. Some clinicians report administering IM injections of fosphenytoin as large as 20 mL in a single site without adverse consequences or serious discomfort.[102] It is also possible to divide his daily dosage into two injections given in two different sites, although many patients prefer to receive fewer injections.

Adverse Effects

CASE 60-5

QUESTION 1: G.R. is a 53-year-old man with partial-onset epilepsy characterized by occasional tonic–clonic seizures. He has taken phenytoin for the past 2 years. His dosage of phenytoin was recently reduced from 400 to 360 mg/day because of symptoms of AED intoxication (mild confusion, occasional diplopia, ataxia, and lateral gaze nystagmus). After the dose reduction, his confusion and diplopia decreased significantly. The neurologic evaluation at the lower dose was within normal limits. No seizures occurred during the subsequent 8 weeks. He continued to complain of being mildly "unsteady" on his feet. He also exhibits mild-to-moderate gingival hyperplasia and significant halitosis. Discuss phenytoin-related gingival hyperplasia and management techniques that may be helpful for G.R. Because G.R.'s seizures are apparently under complete control, is there any problem maintaining him on his current dose of phenytoin?

Gingival Hyperplasia

Gum hyperplasia related to phenytoin is common and troublesome. Prevalence is estimated at 40% to 50% of treated patients.[103] Prevalence and incidence rates, however, are misleading because the occurrence and severity of hyperplasia are related to the dose and serum concentration of phenytoin.[103],[104] Gingival hyperplasia is of obvious cosmetic importance. Also, as in G.R., formation of pockets of tissue leads to difficulties with oral hygiene, and halitosis may result.

The mechanism of phenytoin-induced gingival hyperplasia is not well understood. The drug is excreted in saliva and saliva phenytoin concentrations and hyperplasia are correlated; however, this correlation may simply reflect higher serum concentrations producing a greater pharmacologic effect. Phenytoin may stimulate gingival mast cells to release heparin and other mediators that may encourage synthesis of excessive amounts of new connective tissue by fibroblasts. Local irritation caused by dental plaque and food particles may further stimulate this process.[103],[104]

Three approaches to the treatment of existing hyperplasia[104] are (a) dosage reduction or replacement of phenytoin with an alternative AED, if possible, which will permit partial or complete reversal of hyperplasia; (b) surgical gingivectomy, which will correct the problem temporarily, but hyperplasia eventually recurs; and (c) periodontal treatment, which will eliminate local irritants and maintains oral hygiene. Treatment for existing hyperplasia and prevention of further tissue enlargement is important. Assuming that phenytoin is producing adequate seizure control, a combination of gingivectomy and follow-up periodontal treatment may be the best approach.

Oral hygiene programs appear to reduce the degree and severity of gingival hyperplasia when they are initiated before phenytoin therapy is started.[104] Patients who are beginning phenytoin therapy should be educated about the role of oral hygiene in diminishing this side effect. The use of dental floss, gum stimulators, and water-flossing appliances may be beneficial adjuncts to other oral hygiene techniques.

Neurotoxicity

Patients chronically maintained on intoxicating doses of phenytoin appear to be at risk for developing irreversible cerebellar damage and/or peripheral neuropathy. Cerebellar degeneration, resulting in symptoms such as dysarthria, ataxic gait, intention tremor, and muscular hypotonia, is of particular concern; this complication has been observed after episodes of acute phenytoin intoxication.[105],[106] Generalized seizures also can cause cerebellar degeneration secondary to hypoxia. For this reason, the relative importance of phenytoin in the development of this condition is controversial. Nevertheless, cerebellar degeneration has been reported in several patients without hypoxic seizures.[106],[107]

Symptomatic phenytoin-related peripheral neuropathy is rare, although electrophysiologic evidence of impaired neuronal conduction is found in many patients.[105],[108] Symptomatic patients may complain of paresthesias, muscle weakness, and occasional muscle wasting. Knee and ankle tendon reflexes are absent in 18% of patients on long-term phenytoin therapy; the upper limbs are rarely affected.[109] Although areflexia may be irreversible,[109] electrophysiologic abnormalities may be closely related to excessive serum phenytoin concentrations and are reversible after dosage reduction or discontinuation.[107]

In G.R., the general discomfort of mild phenytoin intoxication and the potential for producing cerebellar degeneration necessitate a therapy alteration. The phenytoin dose should be reduced to 330 mg/day because it may produce adequate seizure control without toxic symptoms. Should seizures recur at this lower dosage, it may be advisable to consider an alternative AED.

Antiepileptic Drug Impact on Bone

Some AEDs have a negative impact on bone density. People with epilepsy treated with these drugs are at increased risk for bone disorders and fractures.[110] Longer duration of AED therapy and exposure to multiple AEDs are thought to predict bone loss. Enzyme-inducing AEDs (carbamazepine, phenytoin, and phenobarbital) have been associated with bone loss and an increased risk for fracture. Valproate, although not an enzyme inducer, is associated with decreased bone mineral density in children.[111] Less is known about the impact of newer AEDs on bone mineral metabolism.[112] Because of the length of phenytoin use, G.R. is at risk. His bone health should be further evaluated by a DEXA scan to examine his bone mineral density. G.R. should be evaluated for other risk factors of reduced bone health (e.g., immobility, poor diet, family history). Oral calcium and vitamin D supplementation should be implemented. Depending on the outcome of evaluation, a change from phenytoin to an AED with less or no effect on bone should be considered.

New-onset Seizures in the Elderly

CASE 60-6

QUESTION 1: J.R., a 74-year-old man with newly diagnosed partial seizures, is referred to the neurology clinic for evaluation and treatment. The etiology of his new-onset seizures is presumed to be a recent cerebral infarct. His seizures are complex partial seizures (he "blacks out" and loses track of time). He has no history of secondarily generalized tonic–clonic convulsions. He has had three seizures in the last 4 weeks. His last seizure resulted in a fall down a flight of stairs. His wife reports that he is more likely to have a seizure if he gets "overtired" or "stressed-out." He is also being treated for hypertension and diabetes. What options are available for the treatment of J.R.'s epilepsy?

There are relatively few head-to-head comparative studies of AEDs in patients with epilepsy. Even fewer studies address the comparative efficacy of AEDs in elderly patients. Three studies, in particular, are important when discussing AED treatment in elderly persons with epilepsy.

Brodie et al.[113] compared lamotrigine (n = 102) with carbamazepine (n = 48) in elderly patients with newly diagnosed epilepsy via a double-blind, randomized, parallel study. Discontinuation rates because of adverse effects (the primary outcome parameter) were higher for carbamazepine (42%) than for lamotrigine (18%). Using time to first seizure as a measure of efficacy, no differences were found between the two AEDs, and the authors

suggested that lamotrigine is “acceptable” as initial treatment in elderly patients with newly diagnosed epilepsy.

Carbamazepine (600 mg/day), gabapentin (1,500 mg/day), and lamotrigine (150 mg/day) were compared for efficacy and tolerability in 593 patients older than 55 years of age (mean age, 72 years) with newly diagnosed epilepsy.[114] Although efficacy was similar in all three groups, study termination for adverse events varied between treatment groups. Carbamazepine had the highest termination rate (31%), followed by gabapentin (21.6%), and then lamotrigine (12.1%) ($P = 0.001$). The authors concluded that lamotrigine and gabapentin should be considered as initial therapy for new-onset seizures in older patients with epilepsy.

Werhahn et al.[115] evaluated carbamazepine (controlled-release), lamotrigine, and levetiracetam in 359 patients 60 years of age and older (mean age, 71.4 years) with newly diagnosed partial epilepsy via a double-blind, randomized, multicenter trial. As with the other two studies, efficacy (as measured by seizure freedom rates), did not differ between the three drugs. But retention rate at week 58 (primary outcome) was significantly higher for levetiracetam (61.5%) than for carbamazepine (45.8%) ($P = 0.02$). The retention rate for lamotrigine (55.6%) was close to that of levetiracetam.

These studies in elderly patients with new-onset epilepsy suggest that gabapentin, lamotrigine or levetiracetam would be good choices for initial treatment of J.R.’s epilepsy. It is noteworthy that none of these AEDs are FDA-approved for newly diagnosed epilepsy.

It is also important to consider drug-interaction profile, dosing frequency, and drug costs when selecting AED therapy. Generally, elderly persons take more medicines than younger individuals. For example, the average number of concomitant medications in the study by Rowan et al.[114] was seven. J.R. is likely to be taking other medicines for diabetes and hypertension. Gabapentin, lamotrigine, nor levetiracetam causes drug–drug interactions, although lamotrigine is influenced more so than gabapentin or levetiracetam by other medicines. Doses of gabapentin and levetiracetam have to be adjusted for renal function.

Adverse Effects

Comparative studies identified minimal differences in efficacy. Newer AEDs, however, showed better tolerability than the older AEDs. In general, elderly patients not only respond to AEDs at lower doses and concentrations but they also exhibit toxicity symptoms at lower doses than do younger patients. Age-related declines in renal and hepatic function may account for those observations. The pharmacokinetics of many AEDs have been studied in the elderly and a decrease in clearance is noted as compared with the young.[116] Decreased clearance of AEDs in the elderly has often been cited as a reason for their increased responsiveness to these drugs.

The impact of AEDs on cognition is an important issue for all patients with epilepsy and perhaps it is an even greater issue in elderly patients.[117–119] As evidenced from the study by Rowan et al.,[114] CNS toxicities such as dizziness, unsteady gait, and ataxia are common adverse effects of AEDs in elderly patients. These symptoms may increase the risk of falls, which are of particular concern in light of the potential negative effects of AEDs on bone mineral density.

J.R. and his family should be informed about the benefits and risks associated with each AED and they should also be incorporated into the decision-making process. AED therapy in the elderly should follow the "start low and go slow" adage, and elderly patients should be monitored for both efficacy (via a seizure calendar) and toxicity (reporting any intolerable side effects).

Absence Seizures

CHOICE OF MEDICATION AND INITIATION OF ETHOSUXIMIDE THERAPY

CASE 60-7

QUESTION 1: T.D., a 7-year-old, 25-kg girl, is reported by her teacher to have three or four episodes of "staring" daily. Each spell lasts 5 to 10 seconds. No convulsive movements occur during the episodes, but her eyelids appear to flutter. She is fully alert afterward. T.D.'s school performance is somewhat below average, despite an intelligence quotient (IQ) of 125. An EEG shows 3-Hertz (Hz) spike-and-wave activity. Typical childhood absence epilepsy is diagnosed. Physical examination and laboratory evaluation findings are normal, and no other positive findings are evident on the neurologic examination. What drug should be prescribed for T.D., and how should therapy with this drug be initiated?

Ethosuximide, valproate, and lamotrigine are commonly used to treat absence epilepsy in the United States. Ethosuximide is a succinimide agent that blocks T-type calcium currents in the thalamus. The drug is effective against absence seizures, but is ineffective against other seizure types. Patients who receive ethosuximide, predominantly children, generally tolerate the drug well and, given its lack of idiosyncratic hepatic toxicity, it has historically been preferred over valproate by many prescribers for the treatment of childhood absence epilepsy. Valproate, a carboxylic acid derivative with broad-spectrum activity against many focal-onset and generalized-onset seizure types, is highly effective but is associated with adverse effects (dose-related, non-dose-related, and severe idiosyncratic) that limits the drug's use among some patient groups. In addition to ethosuximide and valproate, lamotrigine also has been recommended as an initial monotherapy agent for treatment of absence epilepsy, although it is not FDA-approved for this indication[120–122] (Tables 60-2 and 60-6).

Valproate, ethosuximide, and lamotrigine were directly compared for efficacy in the treatment of newly diagnosed childhood absence epilepsy.[123] Efficacy rates for valproate and ethosuximide (based on freedom from treatment failure) were not significantly different, but were significantly higher than for lamotrigine. Attentional dysfunction was significantly more common with valproate than with ethosuximide. Valproate was also more efficacious than lamotrigine for treatment of idiopathic generalized seizures (including absence) in the Standard and New Antiepileptic Drugs (SANAD) trial.[124] Most authorities now consider ethosuximide the drug of first choice for treatment of absence seizures. Valproate is more likely to cause significant nausea and initial drowsiness and it is more likely to interact with other drugs, including AEDs. Valproate usually is reserved for patients whose absence seizures do not respond to ethosuximide.[125] Clonazepam, a benzodiazepine, often is effective for control of absence seizures. Therapy with this drug is limited by prominent CNS side effects (sedation, ataxia, and mood changes) and development of tolerance to its antiepileptic effect after long-term use.[126] Most authorities consider clonazepam a fourth-choice drug for treatment of absence seizures.

T.D. should be started on ethosuximide at a dosage of 15 to 20 mg/kg/day or 250 mg twice daily. The daily dose can be increased by 250 mg every 10 to 14 days as necessary to control seizures. Because the average half-life of ethosuximide in children is ~30 hours, a delay of 10 to 14 days between dosage increments allows ~7 days for achievement of steady state and 7 days for assessment of response.[30]

Patient or Caregiver Education

Educating T.D. and her parents regarding the importance of regular drug administration is extremely helpful in ensuring successful therapy. Nonadherence is common in patients taking AEDs, and rapid discontinuation of these drugs (often secondary to nonadherence) may precipitate status epilepticus. The concept that medication controls rather than cures the seizure disorder should be strongly reinforced. It is also critical to inform both the parents and T.D. that a therapeutic response may not occur immediately and that dosage adjustments may be necessary.

Table 60-7

Common Drugs for the Treatment of Absence Seizures

AED	Regimen	Adverse Effects	Comments
Valproate (Depakene,	Initial 5–10 mg/kg/day (sprinkle caps or syrup); then ↑ by 5–10	GI upset, hair loss, appetite stimulation, and	Enteric-coated tablets or capsules or ER tablets

Depakote, Depakote-ER)	mg/kg/day weekly to therapeutic effect or target serum concentration. Manufacturer's recommended usual maximal dose of 60 mg/kg/day often must be exceeded clinically (especially for patients receiving enzyme-inducing AED) to achieve optimal clinical results. Daily dosing recommended for ER product; doses should be 8%–20% higher than non-ER products	weight gain common. Dose-related tremor and thrombocytopenia may occur. Serious hepatotoxicity extremely rare with monotherapy and in patients younger than 2 years of age	may ↓ GI toxicity. Time to peak serum concentrations delayed for 3–8 hours with enteric coating; longer delay if given with food; serum concentrations must be interpreted carefully. Also effective against primarily generalized tonic–clonic seizures. Monitor LFTs and platelet count
Lamotrigine (Lamictal)	See Table 60-6		
Ethosuximide (Zarontin)	Initial 20 mg/kg/day or 250 mg daily or BID; then ↑ by 250 mg/day every 2 weeks to therapeutic effect or target serum concentration	GI upset and sedation common with large single dose, especially on initiation. Daily divided doses may be necessary despite long half-life. Leukopenia (mild, transient) in up to 7%; serious hematologic toxicity extremely rare	Parents/patient should be informed that GI effects and sedation may occur but tolerance usually develops. No good evidence it precipitates tonic–clonic seizures. Up to 50% of patients with absence may exhibit tonic–clonic seizures independent of ethosuximide

AED, antiepileptic drug; BID, 2 times daily; ER, extended release; GI, gastrointestinal.

Therapeutic Monitoring

CASE 60-7, QUESTION 2: What subjective or objective clinical data should be monitored in T.D. for evidence of ethosuximide's therapeutic and adverse effects?

T.D.'s seizure frequency and any side effects she experiences are the primary monitoring parameters. If ethosuximide serum concentrations are used to assist in dosing, 40 to 100 mcg/mL is the usual target range; however, a clearly defined toxicity syndrome does not reliably develop when ethosuximide serum concentrations exceed 100 mcg/mL. Gradual and cautious increases in ethosuximide dosage when serum concentrations are beyond the upper limits of the "usual therapeutic range" may improve response in resistant patients. Although ethosuximide traditionally is administered in divided doses, its long half-life allows successful use of single daily doses for many patients. Clinicians should be alert to acute side effects of nausea and vomiting that are associated with large single doses of ethosuximide; should these occur, divided daily doses may be necessary.[30]

Laboratory monitoring for idiosyncratic hematologic toxicity from ethosuximide often is recommended. Ethosuximide causes neutropenia in approximately 7% of patients. Although this reaction often is transient, even if the drug is continued, rare patients may exhibit fatal pancytopenia. Presumably, early detection of neutropenia by means of periodic CBC will allow discontinuation of the drug and potential reversal of this adverse effect.[127] These hematologic reactions, however, can occur unpredictably at any time during therapy and often are missed by routine laboratory monitoring. Patient or caregiver education regarding signs and symptoms associated with leukopenia and pancytopenia (e.g., sudden onset of severe sore throat with oral lesions, easy bruisability, increased bleeding tendency) and instructions to consult the physician if these symptoms occur may be more important than laboratory monitoring.[57]

T.D.'s parents should be informed that nausea or sedation may occur with initiation of ethosuximide. Tolerance to these effects usually develops, although temporary dose reductions may be necessary.

Generalized Tonic–Clonic Seizures Accompanying Absence Seizures

CASE 60-7, QUESTION 3: Three months later, T.D.'s absence seizures have been reduced to a frequency of one every 2 weeks with an ethosuximide dosage of 750 mg/day. Her initial drowsiness has almost disappeared, and nausea was alleviated by administering doses with food. She has, however, experienced two tonic–clonic convulsions in the past month. Both seizures were witnessed by her parents and were well described. No auras or signs of focal seizure activity were apparent, and each episode consisted of typical tonic–clonic activity lasting 1 to 2 minutes. T.D. was incontinent of urine on both occasions, and postictal confusion and drowsiness were significant. Physical examination and laboratory testing showed no abnormalities. A repeat EEG continued to show infrequent 3-Hz spike-and-wave discharges; no abnormal focal discharges were noted. What is the relationship between T.D.'s tonic–clonic seizures and ethosuximide therapy?

It is commonly believed, and often stated in the literature, that ethosuximide may precipitate or worsen tonic–clonic seizures; however, this effect has not been clearly demonstrated. As many as 50% of patients who initially present with absence seizures also experience tonic–clonic seizures.[128] Historically, it had been common practice to add another AED (e.g., phenobarbital or phenytoin) to ethosuximide therapy to prevent this.[129] However, routine use of drugs for prophylaxis of tonic–clonic seizures may increase the risk of toxicity and potentially reduce adherence with medication regimens. Sedative drugs, especially phenobarbital, actually may aggravate absence seizures in some patients.[130]

In summary, subsequent generalized tonic–clonic seizures are common in patients who initially experience absence spells. It is unlikely that ethosuximide played a causative role for this development in T.D.

ASSESSMENT REGARDING NEED FOR ALTERATION IN ANTIEPILEPTIC DRUG THERAPY AND CHOICE OF ALTERNATIVE ANTIEPILEPTIC DRUG

CASE 60-7, QUESTION 4: What alterations are indicated in T.D.'s drug therapy because of the appearance of generalized tonic–clonic seizures?

Drug therapy for prevention of further tonic–clonic seizures is indicated. Phenytoin, carbamazepine, or valproate might be considered for use in T.D. Owing to her age and sex, many clinicians would avoid using phenytoin because of its dysmorphic and cosmetic side effects. Carbamazepine is widely used for secondarily generalized tonic–clonic seizures and some cases of tonic–clonic seizures in children. It lacks many of the troublesome, common side effects associated with phenytoin. Carbamazepine, however, is not effective for control of absence seizures. Therefore, it is likely that both ethosuximide and carbamazepine would be needed by T.D. Carbamazepine also has been associated with exacerbation of seizures (including atonic, myoclonic, and absence seizures) in children with mixed seizure disorders who exhibit bilaterally synchronous 2.5- to 3-Hz discharges on the EEG.[131],[132] The need for polytherapy and the possible risk of seizure exacerbation make carbamazepine a less attractive treatment option for T.D.

Valproate is effective for controlling both absence and primary generalized tonic–clonic seizures.[39],[51] T.D. appears to have primary generalized tonic–clonic convulsions; focal signs (e.g., unilateral or single limb involvement) were not observed, and focal discharges (e.g., isolated abnormal electrical activity localized to one portion of the brain) were not found on the EEG. Although neither observation completely rules out secondarily generalized tonic–clonic seizures, the likelihood seems low. Therefore, valproate may offer advantages over carbamazepine in terms of efficacy. In addition, both of T.D.'s seizure types potentially could be controlled with a single medication.

VALPROATE THERAPY

Initiation and Dosage

CASE 60-7, QUESTION 5: T.D.'s physician elects to use valproate. The therapeutic goal is control of her seizures with valproate alone. What procedure should be followed regarding discontinuation of ethosuximide and initiation of valproate?

Techniques used by clinicians to substitute one AED for another depend largely on experience and judgment. Generally, it is best to attain a potentially therapeutic dose of a new medication before attempting to discontinue the previous drug. Serum concentration monitoring may be helpful for some AEDs. Ethosuximide has a relatively long half-life, whereas valproate's half-life is short. Therefore, if necessary, steady state serum concentrations of valproate can be established and evaluated rapidly; evaluation of the effect of decreases in the ethosuximide dosage must await the prolonged elimination of this drug. Once a desired valproate dose or serum concentration has been achieved, the ethosuximide dosage can be reduced gradually by 250 mg/day every 2 to 4 weeks.

Valproate should be initiated at 125 to 250 mg twice daily. Valproic acid syrup or capsules or divalproex sodium can be used. Divalproex often is preferred because it may cause fewer GI side effects than valproic acid. Syrup forms of valproate probably should be avoided unless extremely small doses are required (e.g., infants) or patients cannot swallow. Valproate syrup has an unpleasant taste, and its rapid absorption increases the likelihood of acute, dose-related side effects such as nausea. Lower initial valproate doses are less likely to cause acute side effects (e.g., drowsiness and GI upset). Weekly dosage increases of 5 to 10 mg/kg/day usually are well tolerated and would be appropriate for T.D. More rapid increases may be desirable if tonic–clonic seizures occur frequently. The maximal recommended dosage of valproate is 60 mg/kg/day. Many patients, especially those receiving enzyme-inducing drugs, require higher-than-recommended doses to achieve adequate clinical effect; other patients may respond at much lower doses. Valproate can be titrated in T.D. to produce a "target" serum concentration of approximately 75 mcg/mL. Because ethosuximide is withdrawn, the valproate dose can be further adjusted on the basis of seizure frequency and side effects.

Dosage Forms

CASE 60-7, QUESTION 6: T.D. has been taking valproic acid capsules, 250 mg TID, for 3 weeks. Ethosuximide was discontinued 2 weeks ago; at that time, a valproate serum level just before her morning dose was 68 mcg/mL. She has not experienced generalized tonic–clonic seizures for 6 weeks but continues to have an absence seizure every 2 to 3 weeks. T.D. complains of nausea, epigastric burning pain, and occasional vomiting lasting approximately 1 hour after her doses of valproate. All recent laboratory tests were within normal limits. Administration of the drug with meals is only partially helpful. What alterations can be made in T.D.'s dosing regimen to relieve these symptoms and possibly improve seizure control?

T.D. appears to be a candidate for the use of an enteric-coated valproate preparation or extended-release divalproex. Divalproex tablets are available as an enteric-coated delayed-release preparation, which causes delayed rather than extended absorption of valproate; therefore, these tablets are not a sustained-release product formulation. When patients are switched from nonenteric-coated formulations to divalproex tablets, the frequency of administration should not be decreased. Valproic acid and enteric-coated dosage forms of valproic acid or divalproex are completely absorbed; these can be interconverted at the same total daily dose of medication.[133],[134] An extended-release formulation of divalproex sodium is also available that can be administered as a single daily dose. Extended-release divalproex (divalproex ER), however, is not bioequivalent to other dosage forms of valproate.[135] When equal doses are administered, the ER formulation produces serum concentrations that are approximately 89% of those produced by other valproate dosage forms. Accordingly, when patients are converted to divalproex ER from other forms of valproate, the manufacturer recommends an increase of 8% to 20% in the administered dose. T.D.'s valproic acid capsules can be replaced with an equal daily dose of divalproex tablets. Divalproex should be administered on a 3-times-daily dosing schedule. Alternatively, T.D. could be given 1,000 mg of divalproex ER once daily. The results of this change should be apparent within approximately 1 week. By that time, significant relief from GI side effects should have occurred. It may then be possible to increase the dose of divalproex in an effort to improve seizure control.

Capsules containing enteric-coated beads of divalproex also are available; the 125-mg capsule contents can be dispersed in food for administration to children or others who have difficulty swallowing tablets or capsules. In addition, use of the "cap" end of the capsule to measure half of the contents can approximate doses of 62.5 mg.

Pharmacokinetics and Serum Concentration Monitoring

CASE 60-7, QUESTION 7: Two weeks later, T.D. returns for follow-up. Her GI symptoms have resolved. She has been taking divalproex tablets 250 mg with breakfast and lunch and 375 mg with a bedtime snack for the past week. She has had no seizures in the past 2 weeks and complains of no side effects. A valproate serum level before her morning dose today was 117 mcg/mL (considerably higher than her previous valproate level of 68 mcg/mL). The laboratory reports that duplicate determinations of this level agreed within 5 mcg/mL. T.D. denies taking her medication incorrectly; her parents support this, and the tablet count in her prescription bottle is correct. She has taken no other drugs except a multivitamin. How can this disproportionate increase in her valproate serum concentration be explained, and what is its clinical significance? Does valproate exhibit dose-dependent pharmacokinetics?

The observed changes in T.D.'s valproate serum concentrations are probably not the result of dose-dependent metabolism as is seen with phenytoin; instead, these changes are more readily explained by the absorption characteristics of divalproex tablets. Peak serum concentrations of valproate after administration of divalproex may be delayed for 3 to 8 hours, and administration of food may further delay absorption.[136] In addition, diurnal fluctuation in both the rate and extent of absorption of divalproex may be significant. Absorption may be reduced by approximately one-third and peak plasma concentrations may be delayed for up to 12 hours for divalproex doses administered in the evening.[32] Twelve to 15 hours probably elapsed between the administration of T.D.'s last dose and blood sampling; therefore, the currently reported blood level may more closely approximate a peak concentration. Previous blood levels, determined while she was receiving rapidly absorbed valproic acid capsules, are more likely to have been trough concentrations. T.D.'s adherence to her prescribed dosage regimen also may have increased because of the change in dosage form and reduced side effects; her previous serum concentrations may not have reflected administration of the prescribed dose.

Other pharmacokinetic factors may have actually moderated this unusual increase in valproate concentrations. Valproate concentrations may fluctuate throughout the day in a pattern that does not reflect the timing of doses.[137] This fluctuation may be partially related to changes in serum concentrations of endogenous fatty acids that displace valproate from protein-binding sites. Valproate's hepatic clearance is restrictive (i.e., valproate has a low extraction ratio and its clearance is limited by the free fraction of drug in plasma); therefore, when protein-binding displacement occurs, free fraction of drug in plasma and clearance increase. As a result, free serum concentrations of valproate increase only transiently, whereas total serum concentrations decrease persistently. Valproate also exhibits dose dependency in its binding to serum proteins. As concentrations approach 70 to 80 mcg/mL, binding sites on albumin molecules become saturated, and the free fraction of drug in plasma increases.[30],[133] This effect also increases valproate clearance and reduces total serum concentrations. Both of these effects may actually "dampen" the apparent increase in plasma concentrations seen in T.D. When also considering the poorly established "therapeutic range" for this drug, it becomes apparent that monitoring serum concentrations is a less useful tool in valproate therapy than with some other AEDs.[133]

The clinical significance of T.D.'s elevated valproate serum concentrations is minimal. She is not experiencing symptoms suggestive of valproate toxicity, and it is too soon after the dosage increase to assess the effect of this change on her seizure frequency. Therefore, alteration in her drug therapy is unnecessary at present and might only confuse evaluation of her response to this drug. She should be observed for an additional 4 to 6 weeks to evaluate seizure frequency before further alterations in her dosing regimen are considered. Further increases in her dosage are not contraindicated as long as she is tolerating the medication and such increases are justified on the basis of seizure frequency.

Hepatotoxicity

CASE 60-7, QUESTION 8: Two months later, T.D. is taking 375 mg of divalproex TID with meals. She has had no absence seizures for 5 weeks and no generalized tonic–clonic seizures for 10 weeks. Yesterday, her valproate plasma concentration was 132 mcg/mL. In addition, her alanine aminotransferase (ALT) was 32 international units/mL and her aspartate aminotransferase (AST) was 41 international units/mL. All other laboratory tests (bilirubin, alkaline phosphatase, lactate dehydrogenase, prothrombin time, and serum albumin) were normal. T.D.'s LFTs have been monitored monthly since she began taking valproate, and they were previously normal. Physical examination was negative for scleral icterus, abdominal pain, or other signs of liver disease. Discuss these laboratory abnormalities and physical findings in relation to possible valproate-induced hepatotoxicity in T.D.

Liver damage related to valproate therapy appears to be caused by accumulation of hepatotoxic metabolites of valproate (probably 4-en-valproate) in certain patients.[138],[139] These metabolites may be formed in larger quantities in patients who also receive enzyme-inducing drugs such as phenobarbital. Most cases of fatal hepatotoxicity have occurred in young (<2 years of age) patients with neurologic and metabolic abnormalities who also had severe, difficult-to-control seizures and who were taking multiple AEDs.[138–143] It is important to recognize, however, that severe hepatotoxicity is not limited to this population.[144] Liver damage occurs early in therapy and symptomatically resembles fulminant hepatitis with hepatic failure. Patients may experience vomiting, drowsiness, lethargy, anorexia, edema, and jaundice; these symptoms often precede laboratory evidence of hepatic damage. Liver biopsies in affected patients show evidence of hepatic necrosis and steatosis. Death results from hepatic failure or a Reye-like syndrome.[139],[141],[145]

Asymptomatic elevations in liver enzymes (such as those found in T.D.) occur commonly during the first 6 months of treatment with valproate and usually are not associated with severe or potentially fatal valproate-induced hepatotoxicity. These changes in aminotransferase usually disappear without alteration in therapy; in some cases, temporary dosage reduction is followed by normalization of laboratory tests within 4 to 6 weeks.[139],[141] Without systemic symptoms or other signs of significant liver damage, it is unlikely that the laboratory abnormalities observed in T.D. represent severe liver toxicity from valproate. Because T.D. is responding well to valproate therapy, no change in therapy is warranted at this time. Laboratory testing probably can be repeated in 4 to 6 weeks. T.D. and her family should be educated regarding the possible signs and symptoms of valproate-induced liver damage and instructed to consult their physician if these symptoms are noted.

Routine Liver Function Tests

CASE 60-7, QUESTION 9: What is the usefulness of routinely monitoring LFTs in patients receiving valproate?

Serious hepatotoxicity related to valproate therapy is extremely rare. Historically, the rate of fatal hepatotoxicity decreased significantly (despite substantial increases in the use of valproate) after the use of the drug in high-risk patients (e.g., the very young) decreased and its use as monotherapy increased. Hepatotoxicity is estimated to occur in less than 0.002% of patients treated with valproate.[139],[140],[142] In children younger than 2 years of age who receive AED polytherapy, the incidence of this complication is 1 in 500 to 1 in 800. Because asymptomatic, apparently benign elevations in liver enzymes are common early in therapy with valproate and symptoms of liver damage often precede laboratory changes, frequent LFTs during early valproate therapy are unlikely to detect serious hepatotoxicity.[57],[139–141,146] Education of caregivers or patients regarding potential symptoms of hepatotoxicity, with careful observation and follow-up by health care professionals, is recommended as the most effective method to monitor for this drug-induced illness.

In predisposed patients (i.e., very young children with associated neurologic abnormalities and those receiving polytherapy), significant increases in LFT values that are noted early in therapy may be clinically significant. At the onset of symptoms suggesting this condition, laboratory testing may help confirm its presence.

Acute Repetitive (Cluster) Seizures

RECTAL DIAZEPAM GEL

CASE 60-8

QUESTION 1: B.N., a 7-year-old, 28-kg boy, has had seizures since age 3 months. He suffered anoxia at birth. His seizures usually involve initial confusion and disorientation, shortly followed by generalized tonic–clonic convulsive activity. Despite treatment with carbamazepine at maximal tolerated doses and serum concentrations (300 mg TID; 9–11 mcg/mL), he continues to have approximately two seizures monthly. Recent trials of topiramate and tiagabine as additions to his carbamazepine were unsuccessful and caused intolerable sedation and lethargy. During the past year, he has been admitted to the emergency department (ED) 5 times because of seizure "flurries" consisting of three to six seizures occurring during a period of 12 or fewer hours. Although he regains consciousness between these "flurry" seizures, he remains lethargic. During ED admissions, IV diazepam was administered. This was rapidly successful in terminating seizure activity. B.N.'s mother relates that she usually can identify the onset of seizure flurries; B.N.'s behavior changes and he becomes "clinging" and "whiny" and hyperactive. She also indicates that the initial seizure in a flurry differs from B.N.'s typical episodes. Before the onset of generalized seizure activity, he experiences much briefer periods of confusion. In addition, the generalized seizures are longer and more severe (often with dramatic cyanosis) at the beginning of a "flurry." Why is prophylactic or abortive therapy for B.N.'s seizure flurries indicated? What factors about B.N. predict successful use of such treatment, and how can it be administered?

Frequent ED visits resulting from cluster seizures are expensive and frightening for many patients and their families. B.N. continues to experience seizure flurries despite carbamazepine therapy. He responds well to IV diazepam and has a caregiver who can identify the onset of seizure clusters. His seizure clusters appear to be distinct from the other seizures that he experiences. All of these factors indicate that a trial of caregiver-administered treatment to abort these cluster episodes is likely to be helpful and should be initiated.

Rectal diazepam gel is available for home administration to patients with acute episodes of repetitive seizure activity.[147] When diazepam gel is administered rectally, peak plasma concentrations occur in approximately 1.5 hours,[148] and cluster seizures are often terminated within 15 minutes. Use of diazepam rectal gel is recommended only when caregivers can recognize the onset of cluster seizures, which are different from a patient's usual seizure activity, and when the caregivers can be trained to administer the preparation safely and to monitor the patient's response (e.g., respiratory status) after administration. Caregivers should be informed that this preparation is not for as needed use with every seizure; it should be used only for identifiable cluster seizures or prolonged seizures.

B.N.'s mother should administer rectal diazepam gel at the onset of identifiable cluster seizure activity. A dose of approximately 0.3 mg/kg (10 mg) should be given and repeated, if necessary, within 4 to 12 hours of the first dose. B.N.'s mother should be counseled on the administration of this product and given the patient package insert, which gives complete instructions for the administration of rectal diazepam. After administration, B.N. should be monitored for at least 4 hours to ensure that no respiratory depression or other adverse side effects are occurring and to assess the effect of the medication on his seizures. The most common adverse effect seen with rectal diazepam is somnolence, occasionally accompanied by dizziness and ataxia. Respiratory depression is very uncommon. IM, buccal, and intranasal formulations of benzodiazepines are currently being investigated for their utility in aborting cluster seizures and their use may address some of the barriers associated with rectal drug administration.[149]

Febrile Seizures

INCIDENCE AND CLASSIFICATION

CASE 60-9

QUESTION 1: J.J., a 14-month-old girl, is brought to the ED after having a generalized tonic–clonic convulsion lasting approximately 5 minutes. The episode occurred in association with an upper respiratory infection. On arrival in the ED, her temperature was 39.5°C rectally. She was alert at that time; all laboratory and neurologic findings, including lumbar puncture, were normal. J.J. has no history of neurologic abnormality. Her 7-year-old brother suffers from both absence and generalized tonic–clonic seizures. What is the relationship between febrile seizures and epilepsy? How may J.J.'s convulsion be classified on the basis of the data available?

Up to 8% of children have a febrile seizure between 6 months and 6 years of age.[150],[151] Simple febrile seizures occur with a fever of greater than or equal to 38°C in previously normal children younger than 5 years of age. They last less than 15 minutes and have no focal features. The associated seizure does not arise from CNS pathology. Complex febrile seizures show focal characteristics or are prolonged longer than 15 minutes. The child may or may not have previous neurologic abnormalities. The risk of occurrence of unprovoked afebrile seizures after a febrile seizure is 4 times greater than in the general population. A family history of afebrile seizures, complex febrile seizures, and pre-existing neurologic abnormality is a risk factor associated with the later development of chronic epilepsy.[150],[151]

J.J.'s seizure appears to be a typical simple febrile seizure that developed in association with her upper respiratory tract infection. The lack of previous neurologic abnormality and normal findings on lumbar puncture and laboratory evaluation help confirm this assessment.

TREATMENT OF ACUTE SEIZURE

CASE 60-9, QUESTION 2: How should J.J.'s febrile seizures be treated?

Because J.J. is not having a seizure at present, AED therapy is not required. Measures to reduce her elevated temperature should be initiated; however, these measures may not reduce the risk of further seizures. Acetaminophen and tepid sponge baths usually are helpful.

If patients experience prolonged or repeated febrile seizures, either diazepam or, less commonly, midazolam may be administered.[151–153] Rectal diazepam gel can be used for this purpose.

PROPHYLAXIS AND CHOICE OF ANTIEPILEPTIC DRUG

CASE 60-9, QUESTION 3: On the basis of the subjective and objective data available for J.J., is AED therapy indicated on a long-term basis? What are the benefits and risks of AED prophylaxis for febrile seizures?

Long-term treatment or prophylaxis with AED for simple febrile seizures is not recommended. Up to 54% of affected patients will have recurrent febrile seizures, and the risk of recurrence is even greater when the first episode occurs before 13 months of age. Nonetheless, recurrent febrile seizures are not associated with brain damage or development of epilepsy.[150] Although administration of continuous AED treatment may reduce the recurrence rate of febrile seizures, published guidelines recommend against this practice due to the associated adverse effects.[154]

Prophylactic administration of various fast-acting agents, given during fever episodes, has been studied as an alternative to continuous treatment for the prevention of febrile seizures. Agents in both the AED and antipyretic drug classes have been studied in this regard, but no clinically important benefits have been found.[155–159] Thus, AED prophylaxis for febrile seizures is probably not warranted for J.J., even though she is at risk for both development of epilepsy and recurrence of febrile seizures. No evidence supports that medication will significantly affect her later development of epilepsy. Close medical follow-up of J.J. is warranted. Her parents should be counseled to contact a physician if J.J.'s febrile seizure is accompanied by focal features or last longer than 15 minutes; or, if J.J. experiences afebrile seizures. Although antipyretic measures (tepid sponge baths, acetaminophen or ibuprofen) are of questionable benefit, they can be considered at the onset of fever because these interventions are usually safe and well tolerated. Many febrile seizures occur early in the course of an illness before fever is detected[160]; nevertheless, vigilance by her parents and early antipyretic therapy may help prevent further febrile seizures.

Skin Rash: Hypersensitivity Reactions to Antiepileptic

Drugs

CASE 60-10

QUESTION 1: R.S., a 34-year-old man, has been taking phenytoin 200 mg BID for the past 7 weeks to control complex partial and secondarily generalized tonic–clonic seizures. Seizures began approximately 4 months ago after surgical evacuation of a subdural hematoma. Today he appears at the walk-in clinic and complains of an "itchy rash" that began 2 days ago. He describes "feeling lousy" for the past week. On examination he is febrile (38.5°C orally). A maculopapular, scaly, erythematous rash covers his upper extremities and torso, and the mucous membranes of his mouth appear to be mildly inflamed. Cervical lymphadenopathy is noted, and the liver is found to be enlarged and tender. R.S. also relates that his urine has become very dark in the past 2 days and that his stools are light colored. What is the significance of R.S.'s skin rash and other signs and symptoms? Are these likely to be related to his phenytoin therapy?

Skin-related adverse reactions (e.g., rash, urticarial) are relatively common (2%–3% of patients) side effects related to AED therapy. Skin rash is most commonly associated with phenytoin, lamotrigine, carbamazepine, and phenobarbital. Most cases are relatively mild, but severely affected patients may exhibit Stevens–Johnson syndrome or a systemic hypersensitivity syndrome accompanied by severe hepatic damage. In R.S.'s case, signs and symptoms suggesting hepatic involvement accompany the skin rash. Fever, lymphadenopathy, and apparent inflammation of mucous membranes also suggest a hypersensitivity reaction to phenytoin with multisystem involvement and the potential for progression to Stevens–Johnson syndrome. Viral infection (e.g., hepatitis, influenza, infectious mononucleosis) should be considered and ruled out as a possible cause of R.S.'s symptoms before they are attributed to phenytoin therapy.[161–164]

DRESS syndrome (which stands for Drug Reaction with Eosinophilia and Systemic Symptoms) is a type of hypersensitivity syndrome that can occur with some drugs, including phenytoin and other AEDs, that is most commonly seen in adults. Typically, patients with this syndrome present with complaints of fever, skin rash, and lymphadenopathy during the first 2 months of AED therapy. Hepatomegaly, splenomegaly, jaundice, or bleeding manifestations may occur. Laboratory manifestations often include leukocytosis with eosinophilia, elevated serum bilirubin, and elevated AST and ALT. When a phenytoin hypersensitivity reaction includes significant hepatotoxicity, fatality may occur in as many as 38% of affected patients.[161]

A high likelihood exists that R.S. has developed a severe reaction to phenytoin; the clinical manifestations and the timing of their appearance are typical of this reaction. Phenytoin should be discontinued immediately pending diagnostic clarification. R.S. should be hospitalized for evaluation of other possible causes of his symptoms such as viral illness and treatment. Treatment of phenytoin-related hypersensitivity and hepatotoxicity is symptomatic and supportive. Intensive therapy with corticosteroids has commonly been used, although little objective evidence exists for beneficial effects of this treatment. Potential complications of this reaction include sepsis and hepatic failure; these conditions should be treated specifically.

CASE 60-10, QUESTION 2: R.S. was hospitalized and treated with oral prednisone and topical corticosteroids. Other potential causes for his condition were ruled out, and his signs and symptoms were attributed to cutaneous and systemic phenytoin hypersensitivity. His fever resolved within 5 days; the skin rash became exfoliative but resolved without infectious complications. Laboratory parameters began to normalize after 10 days. While he was hospitalized, R.S. experienced three generalized tonic–clonic seizures that were treated acutely with administration of IV lorazepam. R.S. was afebrile at the time these episodes occurred. What information regarding the pathogenesis of phenytoin hypersensitivity and hepatotoxicity can be used to guide selection of an alternative AED for R.S.?

Further administration of phenytoin to R.S. is contraindicated on the basis of his history of a severe hypersensitivity reaction to this drug. Although the mechanism of this reaction is not fully understood, research implicates reactive arene oxide metabolites

---

of phenytoin (and other chemically similar AEDs) as possible causative agents for hypersensitivity reactions. Affected patients purportedly are predisposed genetically to the development of hypersensitivity, possibly because a relative deficiency of epoxide hydrolase enzymes allows the accumulation of toxic concentrations of reactive epoxide metabolites. These metabolites are believed to exert a direct cytotoxic effect and to interact with cellular macromolecules, thereby functioning as haptens that stimulate an immunologic reaction.[165],[166] Carbamazepine, phenytoin, and phenobarbital all are metabolized by similar pathways and converted to reactive arene oxides. It is hypothesized that carbamazepine-induced liver damage also may result from the effects of accumulation of reactive epoxide metabolites; these reactive metabolites differ from the 10,11-epoxide metabolite that accumulates during carbamazepine therapy. For this reason, these drugs potentially cross-react in susceptible patients. Cases of apparent cross-reactivity between phenytoin and phenobarbital or carbamazepine have been documented.[167–169] In addition, both carbamazepine and phenobarbital can produce hypersensitivity reactions similar to those seen with phenytoin. This potential for cross-reactivity should be considered when an alternative AED is selected for R.S. An analysis of cases of AED-related skin rashes found that the most significant nondrug predictor of skin rash was the occurrence of a rash with another AED.[170]

Valproate has been suggested as the preferred alternative AED for patients who have exhibited hypersensitivity reactions to phenytoin.[168] Valproate is not metabolized to arene oxides and also is chemically dissimilar to all other AEDs. Because valproate often shows good efficacy for complex partial seizures with secondary generalization, it would seem to be a safe and potentially effective alternative AED for R.S. Of the newer AEDs, lamotrigine should probably be avoided in R.S. because of its likelihood of causing skin rash and apparent hypersensitivity reactions. Oxcarbazepine is potentially an alternative AED for R.S.

because it is not metabolized through the arene oxide pathway. Nevertheless, 25% to 30% of patients who experience a rash in response to carbamazepine will also experience a rash with oxcarbazepine.[171] Therefore, many clinicians would avoid oxcarbazepine. Gabapentin, lacosamide, levetiracetam, pregabalin, tiagabine, topiramate, or zonisamide could be considered as alternative medications for R.S. These medications appear less likely to cause skin rash or hypersensitivity reactions.[170],[172]

It is suggested that R.S. be advised to add phenytoin to his list of medication allergies.

Additional recognized genetic risk factors for AED-related hypersensitivity reactions in specific populations are presented in Table 60-6.

WOMEN’S ISSUES IN EPILEPSY

Although epilepsy affects men and women equally, many health issues are of specific importance to women, such as contraceptive interactions with AEDs, teratogenicity, pharmacokinetic changes during pregnancy, breast-feeding, menstrual cycle influences on seizure activity (catamenial epilepsy), AED impact on bone, and sexual dysfunction.[173],[174] It is noteworthy that the latter two issues can also occur in men. A great need exists to educate both health care professionals and patients about the many complex issues facing women with epilepsy.[175]

For women of childbearing potential, prepregnancy planning and counseling are important, because significant AED exposure of the fetus often occurs by the time pregnancy is confirmed. This is especially important because of the potential for unplanned pregnancies from the AED–contraceptive drug interactions. Prepregnancy counseling also should include the importance of at least 0.4 mg/day of folic acid supplementation and medication adherence. Patients should be informed about the risk of teratogenicity and the importance of prenatal care.

Although complete seizure control is desirable for all patients with epilepsy, it is especially favorable for a woman’s seizures to be well controlled before conception. Monotherapy is preferred whenever possible, because the relative risk of birth defects dramatically increases with AED polytherapy.[160],[176] Monotherapy also improves patient adherence. The AED should be given at the lowest effective dose to reduce the possibility of birth defects.[154] Gradual discontinuation of AED before pregnancy may be considered if a woman has been seizure-free for 2 years or longer.

Antiepileptic Drug–Oral Contraceptive Interaction

CASE 60-11

QUESTION 1: P.Z., a 26-year-old woman, experiences complex partial and secondarily generalized tonic–

clonic seizures. She is taking phenytoin 400 mg/day and divalproex 2,000 mg/day. She reports having two or three partial seizures and one generalized seizure every 3 to 4 months. Despite taking Lo/Ovral (norgestrel 0.3 mg with ethinylestradiol 30 mcg), she has just learned she is pregnant. Her last menstrual period was 6 weeks ago. What is the relationship between P.Z.'s apparent contraceptive failure and her AED therapy?

There have been several reports of reduced efficacy of oral contraceptives in patients receiving various AEDs.[177],[178] These reports describe both breakthrough bleeding and pregnancy. Phenobarbital, phenytoin, carbamazepine, oxcarbazepine, eslicarbazepine, perampanel, and felbamate have been shown to increase the metabolism of ethinylestradiol and progestogens.[179] This effect is not associated with valproate, lamotrigine, gabapentin, tiagabine, zonisamide, levetiracetam, lacosamide, or pregabalin.[179] Topiramate in polytherapy and at high dosages (200–800 mg/day) appears to have a mild, though measurable, effect on oral contraceptive pharmacokinetics; apparent clearance of the estrogen component of combined oral contraceptives is increased in patients taking topiramate.[180] In contrast, topiramate monotherapy in lower dosages (50–200 mg/day) has a lesser impact on the pharmacokinetics of the oral contraceptive.[181]

A lack of contraceptive efficacy may present as irregular or breakthrough menstrual bleeding. Decreased efficacy is not always associated with breakthrough bleeding, however. Oral contraceptive doses can be increased to compensate for the effect of an AED.[182] However, estrogens also may exacerbate seizures in some women.[183] Women older than 35 years of age and those who smoke must consider the risk of thromboembolic complications associated with higher doses of contraceptives. A second contraceptive method (e.g., condoms, intrauterine devices, or spermicide) is recommended to avoid contraceptive failure.[170] Tubal ligation is also an alternative. An additional alternative that could be considered is injectable depot medroxyprogesterone acetate. Although there is a lack of clinical studies substantiating its effectiveness in patients on enzyme-inducing AED, the pharmacokinetic characteristics of this agent suggest that its effect is not reduced by enzyme induction. Medroxyprogesterone is a high-clearance drug; its clearance is directly dependent on hepatic blood flow. Thus, enzyme induction would have little effect on the metabolism of this drug when it is administered by injection. Depot medroxyprogesterone acetate may, however, have other negative effects that would limit its choice as an alternative contraceptive in this situation.[184]

Assuming P.Z. was taking her contraceptive pills on a regular basis, it is possible that her enzyme-inducing AED (phenytoin) is responsible for their failure. Patients receiving enzyme-inducing AED should be prospectively informed that this interaction can occur and advised concerning the use of alternative contraceptives (see Chapter 47, Contraception).

Interestingly, a different drug interaction exists between oral contraceptives and lamotrigine. The estrogen component in oral contraceptives increases the clearance of lamotrigine. Lamotrigine clearance may increase twofold when contraceptive steroids are begun and fall by 50% when contraceptive steroids are discontinued. Changes in lamotrigine levels associated with initiation and discontinuation of contraceptive steroids can result in increased seizure activity in some patients and toxicity in others.[185]

Teratogenicity

CASE 60-11, QUESTION 2: What are the risks of teratogenic effects from P.Z.'s medications? What steps might be taken to minimize these risks?

P.Z.'s child is at risk of congenital malformations because of exposure to several potentially teratogenic drugs: estrogen–progestin combination oral contraceptives, valproate, and phenytoin (also see Chapter 49, Obstetric Drug Therapy).

Many AEDs have teratogenic effects.[186] Animal data regarding the teratogenic potential of the new AEDs are encouraging, but conclusions regarding the teratogenic potential of these AEDs cannot be made because of limited experience in pregnant women. A good resource for clinicians to educate women is the American Epilepsy Society and the American Academy of Neurology series of three Practice Parameter updates on management issues for women with epilepsy focused on pregnancy. They deal with obstetric complications and change in seizure frequency; teratogenesis and perinatal outcomes; and vitamin K, folic acid, blood levels, and breast-feeding.[187–189] The authors evaluated the available evidence based on a structured literature review and provide recommendations.

Most AEDs are believed to exert their teratogenic effects (and possibly other adverse effects such as hepatotoxicity) partly via reactive epoxide metabolites.[160] Enhancement of the formation of these metabolites via hepatic enzyme induction (e.g., by carbamazepine or phenobarbital) or inhibition of their breakdown (e.g., through inhibition of epoxide hydrolase by valproate) would increase the risk of teratogenicity. Combined administration of enzyme inducers and valproate (specifically the combination of carbamazepine, phenobarbital, and valproate with or without phenytoin) is associated with an especially high risk of teratogenicity.[190] In addition, each of the present major AEDs has been associated with congenital malformations when administered alone. Meador et al.[191] provide data from 333 pregnancies in women with epilepsy taking an AED in monotherapy and enrolled in the Neurodevelopmental Effects of Antiepileptic Drugs (NEAD) study. Serious adverse outcomes (major malformations and fetal death) were significantly more likely to occur with exposure to valproate (20.3%) than with carbamazepine (8.2%), phenytoin (10.7%), or lamotrigine (1%). In addition to physical malformations, AED exposure in utero has an adverse effect on neurodevelopment.[192] The NEAD study evaluated age-6 IQ and found that valproate-exposed children had significantly lower scores (mean 97), even after controlling for the mother's IQ and seizure type.[193] The age-6 IQ scores were significantly lower for children exposed in utero to valproate compared with scores of children exposed to carbamazepine (mean 105), phenytoin (mean 108), and lamotrigine (mean 108) monotherapy. A European task force of epilepsy experts recommends that, where possible, valproate should be avoided in women of childbearing potential.[194]

Several strategies can be used to reduce the potential adverse effects of AEDs on pregnancy outcomes. If feasible, before conception, seizure control should be optimized using the AED of first choice for the prospective mother's seizure type or epilepsy syndrome. Monotherapy at the lowest effective dose is the goal. Maintenance of adequate folic acid stores before conception and during fetal organogenesis is also important. Folic acid supplementation can reduce the risk of congenital neural tube malformations in infants at risk who are born to women without epilepsy, but folate supplementation does not reliably reduce the teratogenic effects of AED. Nevertheless, supplementation of folic acid (and ensuring adequate folate levels) is recommended. Because about half of pregnancies are unplanned and not evident until weeks after conception, folate supplementation should be given routinely to women of childbearing age with epilepsy. No study has been conducted to determine the optimal dose of folic acid supplementation in patients taking AEDs. Clinicians engage in much discussion of this topic, but the current practices are not evidence-based. Even though this is the case, P.Z. should start taking 4 mg of folic acid supplementation each day.

Physiologic changes in pregnant women may affect the pharmacokinetics of AEDs.[171] Absorption can be influenced by nausea and vomiting. Hepatic metabolism and renal function both increase during pregnancy. The binding capacity of albumin is decreased during pregnancy, resulting in decreased protein binding for highly bound drugs. Unbound fractions of phenobarbital, phenytoin, and valproate increase with decreased concentrations of albumin.[195–197] For drugs predominately metabolized by the liver with a restrictive clearance (e.g., carbamazepine and valproate), decreased protein binding without changes in intrinsic clearance should result in a decrease in total drug concentrations; unbound drug concentrations usually remain unchanged. For drugs with both increased hepatic metabolism and decreased protein binding (e.g., phenytoin and phenobarbital), both total and unbound plasma concentrations decrease, but not necessarily proportionately.

The clearance of lamotrigine increases as pregnancy progresses, presumably related to the impact of estrogen on lamotrigine metabolism.[198] This alteration in clearance changes immediately postpartum. Preliminary data suggest that oxcarbazepine concentrations may also decrease as pregnancy progresses.[199]

The effects of changes in renal function during pregnancy on AED concentrations are not well known.[199] Renal blood flow and glomerular filtration rate increase during pregnancy. Thus, the renal clearance of drugs that are predominately excreted through the kidneys, such as gabapentin, levetiracetam, and pregabalin, may increase during pregnancy.

During pregnancy, serum levels of AEDs (including free serum levels for highly protein-bound drugs) can be monitored. In this case, a prepregnancy level would be optimal for comparison. Dosage adjustments may help to prevent the increase in seizure frequency that is seen in approximately 25% of pregnant women with epilepsy. Because falls and anoxia associated with uncontrolled generalized tonic–clonic seizures may increase the risk to the unborn baby, P.Z. should be educated on the value of adherence to her AED regimen.

For P.Z., it can be presumed that significant exposure of the fetus to any teratogenic influence of AED has already occurred. Optimization of seizure control is now the primary concern for her. Any major alterations in P.Z.'s AED regimen should be made cautiously to avoid precipitating seizures. In addition, she should be instructed to contact the AED pregnancy registry at Massachusetts General Hospital (1-888-233-2334 or www.aedpregnancyregistry.org). Information provided to the registry will aid in the ongoing monitoring of outcomes of babies born to mothers taking AEDs. Reports from this registry have provided

---

risk information on many AEDs and regular visits to their website is helpful to learn the latest.

VITAMIN K SUPPLEMENTATION

Babies born to women with epilepsy who are taking enzyme-inducing AED are at risk of hemorrhage owing to decreased vitamin-K-dependent clotting factors. Although some question the evidence, women taking carbamazepine, phenobarbital, primidone, or phenytoin should receive vitamin K 10 mg orally every day from 36 weeks of gestation until delivery, and babies should also receive vitamin K 1 mg IM at birth.[200]

BREAST-FEEDING

In a lactating woman who is taking medications, the risk of drug exposure to the infant needs to be weighed against the benefits of breast-feeding.[201] All drugs transfer into milk to some extent. The extent of protein binding of the drug is the most important predictor of drug passage into milk.[202],[203] For the AEDs, a large intersubject variability in the milk/plasma (M/P) ratio exists, presumably owing to a difference in volume and composition of the milk. Thus, the M/P ratio is not useful for predicting infant AED exposure. Reviews on AED and breast-feeding are available.[204] For most first-generation AEDs (carbamazepine, phenytoin, valproic acid), breast-feeding results in negligible AED plasma concentrations in the infants.

For the newer AEDs, breast-feeding should be done cautiously and the infant should be monitored for excess AED plasma concentrations and toxicity, if possible. This information should be presented to P.Z. in an appropriate manner. Once she delivers her baby, re-evaluation and optimization of P.Z.'s AED therapy should occur.

STATUS EPILEPTICUS

Characteristics and Pathophysiology

CASE 60-12

QUESTION 1: V.S., a 22-year-old, 85-kg man, was recently diagnosed as having idiopathic epilepsy with generalized tonic–clonic seizures. For the past 3 months, he has been treated with 600 mg/day of carbamazepine, which completely eliminated his seizures. His steady state carbamazepine serum concentration was 10 mcg/mL. While at his parents' home, he had two tonic–clonic seizures, each lasting 3 to 4 minutes. On arrival at the hospital (~30 minutes after the first seizure began), he was noted to be only semiconscious. His blood pressure was 197/104 mm Hg, his pulse was 124 beats/minute, respirations were 23 breaths/minute, and his body temperature was 38°C rectally. Shortly after his arrival, another generalized tonic–clonic seizure began. How does V.S.'s current condition meet accepted diagnostic criteria for status epilepticus? What risks are associated with status epilepticus?

Status epilepticus (SE) is operationally defined as "either continuous seizures lasting at least 5 minutes or 2 or more discrete seizures between which there is incomplete recovery of consciousness."[205] Because V.S. has had three seizures within slightly more than 30 minutes and did not return to his baseline level of consciousness between seizures, his present condition meets this definition. V.S. is experiencing generalized convulsive SE; this is the most common type and it is associated with the greatest risk of systemic and neurologic damage. SE also may be characterized by nonconvulsive seizures that produce a persistent state of impaired consciousness, or by partial seizures (with or without impaired consciousness). These forms of SE are associated with much lower morbidity and mortality than generalized convulsive SE.

Uncontrolled, convulsive SE can cause severe metabolic and hemodynamic alterations. V.S.'s vital signs (tachycardia, elevated blood pressure, increased respiratory rate, and elevated body temperature) are typical for a patient in SE. Prolonged, severe muscle contractions and CNS dysfunction from uncontrolled seizure discharges result in hyperthermia, cardiorespiratory collapse, myoglobinuria, renal failure, and neurologic damage. Even in the absence of convulsive muscle movements, neurologic damage can occur from excessive electrical activity and the resultant alterations in brain metabolism. When seizure activity persists longer than approximately 30 minutes, failure of mechanisms that regulate cerebral blood flow is more likely; this failure accompanies dramatic increases in brain metabolism and demand for glucose and oxygen. Failure to meet the metabolic demands of brain tissue results in accumulation of lactate and cell death. Peripherally, lactate accumulates and serum glucose and electrolytes are altered. After 30 minutes of seizure activity, the body often fails to compensate for increased metabolic demands, and cardiovascular collapse can occur.[206],[207] For these reasons, SE is considered a medical emergency that requires immediate treatment to prevent or lessen both systemic and neurologic damage. Mortality in adults with SE is approximately 20%[205]; fatal outcome is often the result of the condition that precipitated SE (e.g., acute symptomatic causes, such as cardiopulmonary arrest, stroke). Long-term neurologic consequences of severe SE may include cognitive impairment, memory loss, and worsening of seizure disorders.

General Treatment Measures and Antiepileptic Drug Therapy

CASE 60-12, QUESTION 2: Describe a general treatment plan for V.S.'s episode of status epilepticus.

The immediate therapeutic concern in V.S. is to ensure ventilation, stabilize vital signs, and terminate current seizure activity. If possible, an airway should be placed for airway protection and if ventilatory support is needed; however, this may not be possible while he is convulsing. Objects (e.g., spoons, tongue blades) should never be placed into the mouth of a patient during a seizure. If airway placement is impossible, V.S. should be positioned on his side to allow drainage of saliva and mucus from the mouth and prevent aspiration. An IV line should be established using normal saline, and blood should be obtained for serum chemistries (especially glucose and electrolytes), AED serum concentrations, and toxicology screens. Glucose, 25 g (50 mL of 50% dextrose solution) by IV push should be administered to correct any hypoglycemia, which may be responsible for SE. Glucose administration should be preceded by IV thiamine 100 mg or vitamin B complex to prevent Wernicke encephalopathy.[208]

IV administration of rapid-acting anticonvulsant medication should begin as soon as possible to terminate V.S.'s seizure activity. Status epilepticus becomes more resistant to treatment the longer the seizure continues; thus, treatment is more likely to stop seizures the sooner it is administered.[205] For in-hospital treatment of SE, IV medication administration is usually preferred.

CASE 60-12, QUESTION 3: Which anticonvulsants are available for IV administration? Evaluate the available drugs and recommend a drug, dosage, and regimen for initial treatment of SE in V.S.

Lorazepam, phenytoin, and fosphenytoin are the agents most commonly used as IV therapy in the initial treatment of SE.[205],[209] Phenytoin and fosphenytoin are indicated for treatment of SE, but owing to limitations on their rates of infusion, the onset of their peak effect may be delayed. Therefore, phenytoin or fosphenytoin is usually used after initial treatment with lorazepam.

IV sodium valproate (Depacon) is available, but it is not FDA-approved for the treatment of SE. Although the manufacturer recommends that Depacon be administered slowly (<20 mg/minute), it has been administered safely at high doses and faster infusion rates.[208] There is growing experience with the use of IV valproate for SE that fails to respond to lorazepam and phenytoin, and for patients in whom phenytoin is contraindicated (e.g., phenytoin allergy).[209] An IV form of levetiracetam is available. This drug also is FDA-approved only for patients who cannot receive oral dosage forms of levetiracetam. Rapid IV administration of levetiracetam has been used; however, experience with this agent is limited.[210] Lacosamide is also available in an IV formulation and there are several case reports of its successful use for refractory nonconvulsive SE.[211],[212] IV phenobarbital is usually reserved for SE that does not respond to benzodiazepines and phenytoin.[205]

Four IV regimens for generalized convulsive SE were directly compared in one randomized controlled trial.[213] The study evaluated diazepam followed by phenytoin, lorazepam alone, phenobarbital alone, and phenytoin alone. For initial IV treatment of overt generalized SE, lorazepam was more effective than phenytoin alone. Lorazepam was as effective as the other two regimens, and it was easier to use.

IV administration of either diazepam or lorazepam is usually effective for rapid termination of seizure activity in SE.[214] Owing to diazepam's higher lipid solubility, it redistributes from the CNS to peripheral tissues rapidly after administration; this results in a short duration of action (<60 minutes).[215] Lorazepam's lower lipid solubility prevents rapid redistribution and accounts for its longer duration of action.[215] Lorazepam may be effective for up to 72 hours.[216],[217] Owing to this longer duration, lorazepam is the preferred benzodiazepine for immediate treatment of SEs.[208],[209]

Lorazepam 0.1 mg/kg given intravenously at 2 mg/minute would be appropriate initial therapy for V.S. [208] Lorazepam may cause significant venous irritation, and the manufacturer recommends dilution with an equal volume of normal saline solution or water for injection before IV administration. Lorazepam may be repeated after 5 minutes if seizures continue. The efficacy of lorazepam depends on rapid achievement of high serum and CNS concentrations. Although lorazepam can be administered IM, this route should not be used for treatment of SE because it is unlikely that it would achieve serum concentrations necessary for termination of seizure activity and there is little experience with its use for terminating SE. Midazolam given IM has been shown to quickly and effectively terminate SE when used in out-of-hospital settings. This treatment is an acceptable alternative for in-hospital use when IV access is not feasible.[218],[219] The most common adverse effects after IV administration of benzodiazepines are sedation, hypotension, and respiratory arrest.[215] These side effects are usually short-lived and, when adequate facilities are available for assisted ventilation and administration of fluids, they usually can be managed without major risk to the patient. Respiratory depression occurs most commonly in patients who receive multiple IV medications for control of SE.

INTRAVENOUS PHENYTOIN AND FOSPHENYTOIN

CASE 60-12, QUESTION 4: V.S. was given lorazepam 8 mg IV. Seizure activity ceased 2 minutes after the injection was completed. What drug should be administered to V.S. for prolonged control of seizures? Recommend a dose, route, and method of administration.

Continued effective seizure control is important for patients who experience SE. Previously, when diazepam was the benzodiazepine predominantly used for immediate control of SE, a long-acting AED such as phenytoin was routinely administered at the same time to ensure continued suppression of seizure activity. Routine use of phenytoin has been somewhat de-emphasized with increased use of lorazepam[208]; lorazepam's apparent longer duration of effect may make routine use of IV phenytoin less necessary. Nevertheless, many centers still use phenytoin in conjunction with lorazepam.

The availability of fosphenytoin for IV administration has provided an additional option for administration of phenytoin in the treatment of SE, and in most centers, fosphenytoin is preferred over phenytoin. Use of this phenytoin prodrug allows more rapid administration of large IV loading doses of phenytoin with less risk of injection site complications. Fosphenytoin is also better tolerated than phenytoin.[219] Fosphenytoin itself is inactive; the therapeutic effect results from its conversion to phenytoin.[100],[101]

In the U.S., phenytoin (administered as either sodium phenytoin injection or as sodium fosphenytoin injection) is considered the long-acting anticonvulsant of choice for most patients with generalized convulsive SE.[209] Phenytoin causes much less sedation and respiratory depression than drugs such as phenobarbital when it is used in conjunction with IV benzodiazepines.[208] V.S.'s maintenance carbamazepine therapy was previously effective. Without obvious precipitating factors such as head trauma, CNS infection, and drug or alcohol abuse, SE, in a patient with a history of epilepsy, most commonly results from poor adherence with maintenance AED medication. Therefore, IV fosphenytoin is a good choice for re-establishing effective AED therapy for V.S. Phenytoin is an acceptable alternative if fosphenytoin is unavailable.

Loading Dose

Whether or not V.S. has a detectable serum concentration of carbamazepine, he should be given an IV loading dose of either fosphenytoin (20 mg/kg PE IV at 150 mg/minute) or phenytoin (20 mg/kg IV at 50 mg/minute). After administration of either of these loading doses, serum phenytoin concentrations should remain greater than 10 mcg/mL for approximately 24 hours; this will allow time for determination of V.S.'s serum carbamazepine concentration and estimation of an appropriate maintenance dose of oral carbamazepine once oral therapy can be restarted. In this setting, the use of IV phenytoin or fosphenytoin is a temporary measure. V.S.'s previous positive response to carbamazepine indicates that he should likely continue to receive this drug as his oral maintenance medication.

IV phenytoin can be administered by direct injection into a running IV line. The rate of administration should be no faster than 50 mg/minute to minimize the risk of hypotension and acute cardiac arrhythmias. Cardiovascular status (blood pressure, electrocardiogram) should be monitored closely during administration. Hypotension or electrocardiographic abnormalities usually reverse if the administration of phenytoin is slowed or stopped temporarily. Fosphenytoin can be given by either direct IV injection or, after dilution in any suitable IV solution, by infusion at up to 150 mg PE/minute.[100] Absence of propylene glycol as a diluent renders fosphenytoin potentially less likely than phenytoin to cause cardiovascular adverse effects, but this advantage is not well supported.[220] Electrocardiographic and blood pressure monitoring is recommended when this drug is given IV. Pruritus and paresthesias, usually localized to the face and groin, are relatively common side effects during IV fosphenytoin administration. These sensations are not allergic reactions to the medication. Their occurrence is related to the administration rate, and they are reversible with temporary discontinuation or slowing of the injection.[100]

Maintenance Therapy

The undetectable serum carbamazepine concentration appears to confirm the role of nonadherence in this episode of SE. Because V.S. was previously well controlled on 600 mg/day, this would be a reasonable target dose. Because V.S. may not tolerate carbamazepine if restarted at the prior maintenance dose, gradually escalating up to this dose should be initiated as soon as V.S. can take oral medication. V.S. should be counseled regarding the importance of taking his medication according to directions and any potential barriers to adherence should be addressed.

Alternative Therapies for Refractory Status Epilepticus

Phenobarbital may be useful for treatment of SE if the patient cannot tolerate phenytoin or when seizures continue after administration of appropriate loading doses of phenytoin. Patients who receive phenobarbital after being treated with IV benzodiazepines should be monitored closely for respiratory depression because this effect may be additive. Equipment and personnel to provide ventilatory assistance should be available.[208]

Status epilepticus that does not respond to lorazepam and a longer-acting agent (e.g., phenytoin/fosphenytoin, valproate, levetiracetam, phenobarbital, or lacosamide) is considered refractory status epilepticus. From 20% to 40% of patients with SE will progress to refractory status epilepticus. In such circumstances, an alternative longer-acting agent from those mentioned above may be considered; and, in recent years, the use of such "third-line" agents was a common practice. Recently, it has become a more common practice to escalate therapy to the use of an anesthetic agent after failure of second-line therapy.[209] The most commonly used anesthetic agents for refractory status epilepticus are midazolam and propofol; pentobarbital is also sometimes used. Significant respiratory depression is expected with these therapies; patients require intubation and mechanical ventilation. In addition, vasopressors, such as dopamine or dobutamine, may be required to control hypotension. Constant EEG monitoring also is required to assess the anticonvulsant effect of the drug and to gauge the level of anesthesia.

Midazolam is given as a loading dose of 0.2 mg/kg IV and is followed by an IV infusion of 0.2 to 0.6 mg/kg/hour.[208] Many practitioners adjust the infusion rate to either control electrographic seizures and/or to produce a burst-suppression EEG pattern.[221] Most protocols for anesthetic therapy of refractory SE recommend attempts at gradually reducing the dose of medication after 12 to 24 hours of treatment. If clinical or EEG seizure activity recurs, the dose is increased again to produce the desired EEG pattern. Anesthetic agents may need to be continued for several days or even weeks in some patients.

Continuous IV infusions of propofol or midazolam are also useful for refractory SE. These therapies appear to be less likely than pentobarbital to cause severe hypotension that is refractory to vasopressors.[222–225] Because no direct comparative trials of pentobarbital, propofol, and midazolam have been performed, physician familiarity and preference often guide the choice between these agents for the treatment of refractory SE.

CORE PRINCIPLES		CHAPTER CASES
1	Ischemic and hemorrhagic stroke are diseases involving the vascular system of the brain. In the United States, approximately 87% of strokes are ischemic in nature and 13% are hemorrhagic.	**Case 61-1 (Question 1)**
2	Ischemic and hemorrhagic stroke are medical emergencies, requiring prompt medical attention at the first sign of symptoms. Signs and symptoms of cerebrovascular disease usually occur acutely and vary depending on the area of the brain involved. Ischemic and hemorrhagic events have similar symptoms and must be distinguished before initiating treatment.	**Case 61-2 (Question 1)**
3	Primary prevention is vital to reducing the risk of a stroke. Lifestyle modifications and control of risk factors are the mainstay of primary prevention. Important modifiable risk factors include cardiovascular disease, hypertension, obesity, dyslipidemia, diabetes, smoking and physical inactivity. The use of antiplatelet agents is recommended for cardiovascular (including but not specific to stroke) prophylaxis and reasonable for people whose 10-year risk is >10% as estimated by cardiovascular risk calculators (see Core Principle 4).	**Case 61-1 (Questions 1, 2)**
4	Patients with atrial fibrillation and patent foramen ovale require primary prevention pharmacotherapy according to their ischemic stroke risk. Antiplatelet agents or anticoagulants should be used in patients with these conditions, with selection of an agent dependent on patient characteristics.	**Case 61-1 (Question 2)**
5	Secondary prevention of ischemic stroke and transient ischemic attacks involves the use of antiplatelet agents. Selection of an agent is dependent on patient characteristics.	**Case 61-2 (Questions 5,6, 7, 8, 9, 10)**
6	Acute treatment of ischemic strokes includes the use of alteplase given intravenously. Alteplase should be started after confirming an event is ischemic and not hemorrhagic. The treatment window for use of alteplase is limited to 4.5 hours after the onset of neurologic symptoms. Strict criteria for administration of alteplase must be followed to reduce the risk of intracranial hemorrhage (ICH) and hemorrhagic complications should be carefully monitored.	**Case 61-2 (Questions 2, 3, 4, 5)**
7	The strongest risk factor for hemorrhagic stroke because of non-	**Case 61-3 (Question 1)**

	traumatic intracerebral hemorrhage is uncontrolled hypertension. Intracerebral hemorrhage may also occur as a result of an anatomic abnormality in the brain or a disease process, such as a brain tumor. Bleeding disorders, including those induced by anticoagulant drugs, also predispose patients to intracerebral hemorrhage.	
8	Acute treatment of intracerebral hemorrhage focuses on minimizing hemorrhage expansion through careful blood pressure control and reversal of coagulopathies, when appropriate, as well as prevention and management of elevated intracranial pressure.	**Case 61-3 (Questions 2-6)**
9	Modifiable risk factors for hemorrhagic strokes include blood pressure control, smoking cessation, and avoiding excessive alcohol and cocaine use.	**Case 61-3 (Question 7)**

10	Rehabilitation after a cerebrovascular event is essential to patient recovery. Common complications encountered in rehabilitation included spasticity, depression, and neurogenic bowel or bladder. Pharmacotherapy interventions should be directed at each of these complications with the goal of improving the patient's quality of life and ability to function independently.	**Case 61-5 (Question 1)**

ISCHEMIC STROKE, HEMORRHAGIC STROKE, AND TRANSIENT ISCHEMIC ATTACKS

Ischemic stroke, hemorrhagic stroke, and transient ischemic attacks result from either inadequate blood flow to the brain (i.e., cerebral ischemia) with subsequent infarction of the involved portion of the central nervous system (CNS) or hemorrhages into the parenchyma or surrounding structures of the CNS and subsequent neurologic dysfunction. This group of disorders is the fourth leading cause of deaths among adults in the United States.[1]

Definitions

TRANSIENT ISCHEMIC ATTACK

A transient ischemic attack (TIA) is now defined as transient episode of neurologic dysfunction caused by focal brain, spinal cord, or retinal ischemia not associated with permanent cerebral infarction.[2] It used to be described as the clinical condition in which a patient experiences a temporary (lasting less than 24 hours) focal neurologic deficit such as slurred speech, aphasia, weakness or paralysis of a limb, or blindness. However, the original description is no longer valid because it is implied that TIAs are minor and that symptoms disappeared completely, while recent studies and imaging techniques have shown that TIA can actually lead to brain injury and increased risk of recurrent stroke. Some would argue that TIA term should not be even used at all.

ISCHEMIC STROKE

Ischemic stroke is defined as an infarction of the CNS. Unlike TIAs, ischemic stroke may be either symptomatic or silent.[2] Clinical signs of focal or global cerebral, spinal or retinal dysfunction caused by a CNS infarction are the manifestation of a symptomatic stroke. The two primary causes of infarction and persistent ischemia are atherosclerosis of cerebral blood vessels or an embolus to the cerebral arteries from a distant clot.

INTRACRANIAL HEMORRHAGE

Intracranial hemorrhage involves movement of blood from blood vessels inside the brain into the brain tissue, or parenchyma, and its surrounding structures. Clinical symptoms associated with intracranial hemorrhage are similar to but often more severe than those because of ischemic strokes. These symptoms commonly include neurologic deficits as well as headache, vomiting, and a decreased level of consciousness. Some patients may experience other symptoms including seizures, EKG abnormalities, and a stiff neck. Depending on the type and size of intracranial hemorrhage, symptoms may develop abruptly or worsen slowly over minutes to hours.

The location of the hemorrhage within the intracranial vault determines the type of intracranial hemorrhage. Intracerebral hemorrhages (ICHs) occur when blood moves into the brain parenchyma, whereas other types of hemorrhages develop when blood moves into spaces around the brain tissue.

Epidemiology

Each year an estimated 795,000 individuals in the United States experience a new or recurrent stroke and approximately 610,000 of these are first attacks. It is the fourth most common cause of death in adults after diseases of the heart, cancer, and chronic lower respiratory disease. There is a higher regional incidence and prevalence of stroke and a higher stroke mortality rate in the southern United States than in the rest of the country. Younger men have a higher incidence of stroke than women in the same age group; however, in age group >75 years, women have a higher incidence. Blacks and Hispanics have an increased risk of stroke compared with whites in the United States. The precise reasons for these differences are unclear, but genetic, geographic, dietary, and cultural factors have been considered.[3] In addition, the incidence of risk factors for stroke such as hypertension, diabetes, and hypercholesterolemia differs among racial groups.

In the United States ischemic stroke is the most common type of infarction (Fig. 61-1). Atherothrombotic disease of the large cerebral blood vessels is responsible for the majority of cerebral ischemic events and infarctions. Disease of penetrating arteries that are responsible for oxygenation and nutrition of the CNS, thromboembolic causes (e.g., atrial fibrillation), and other causes such as infection or inflammation of arteries are also responsible for ischemic stroke.

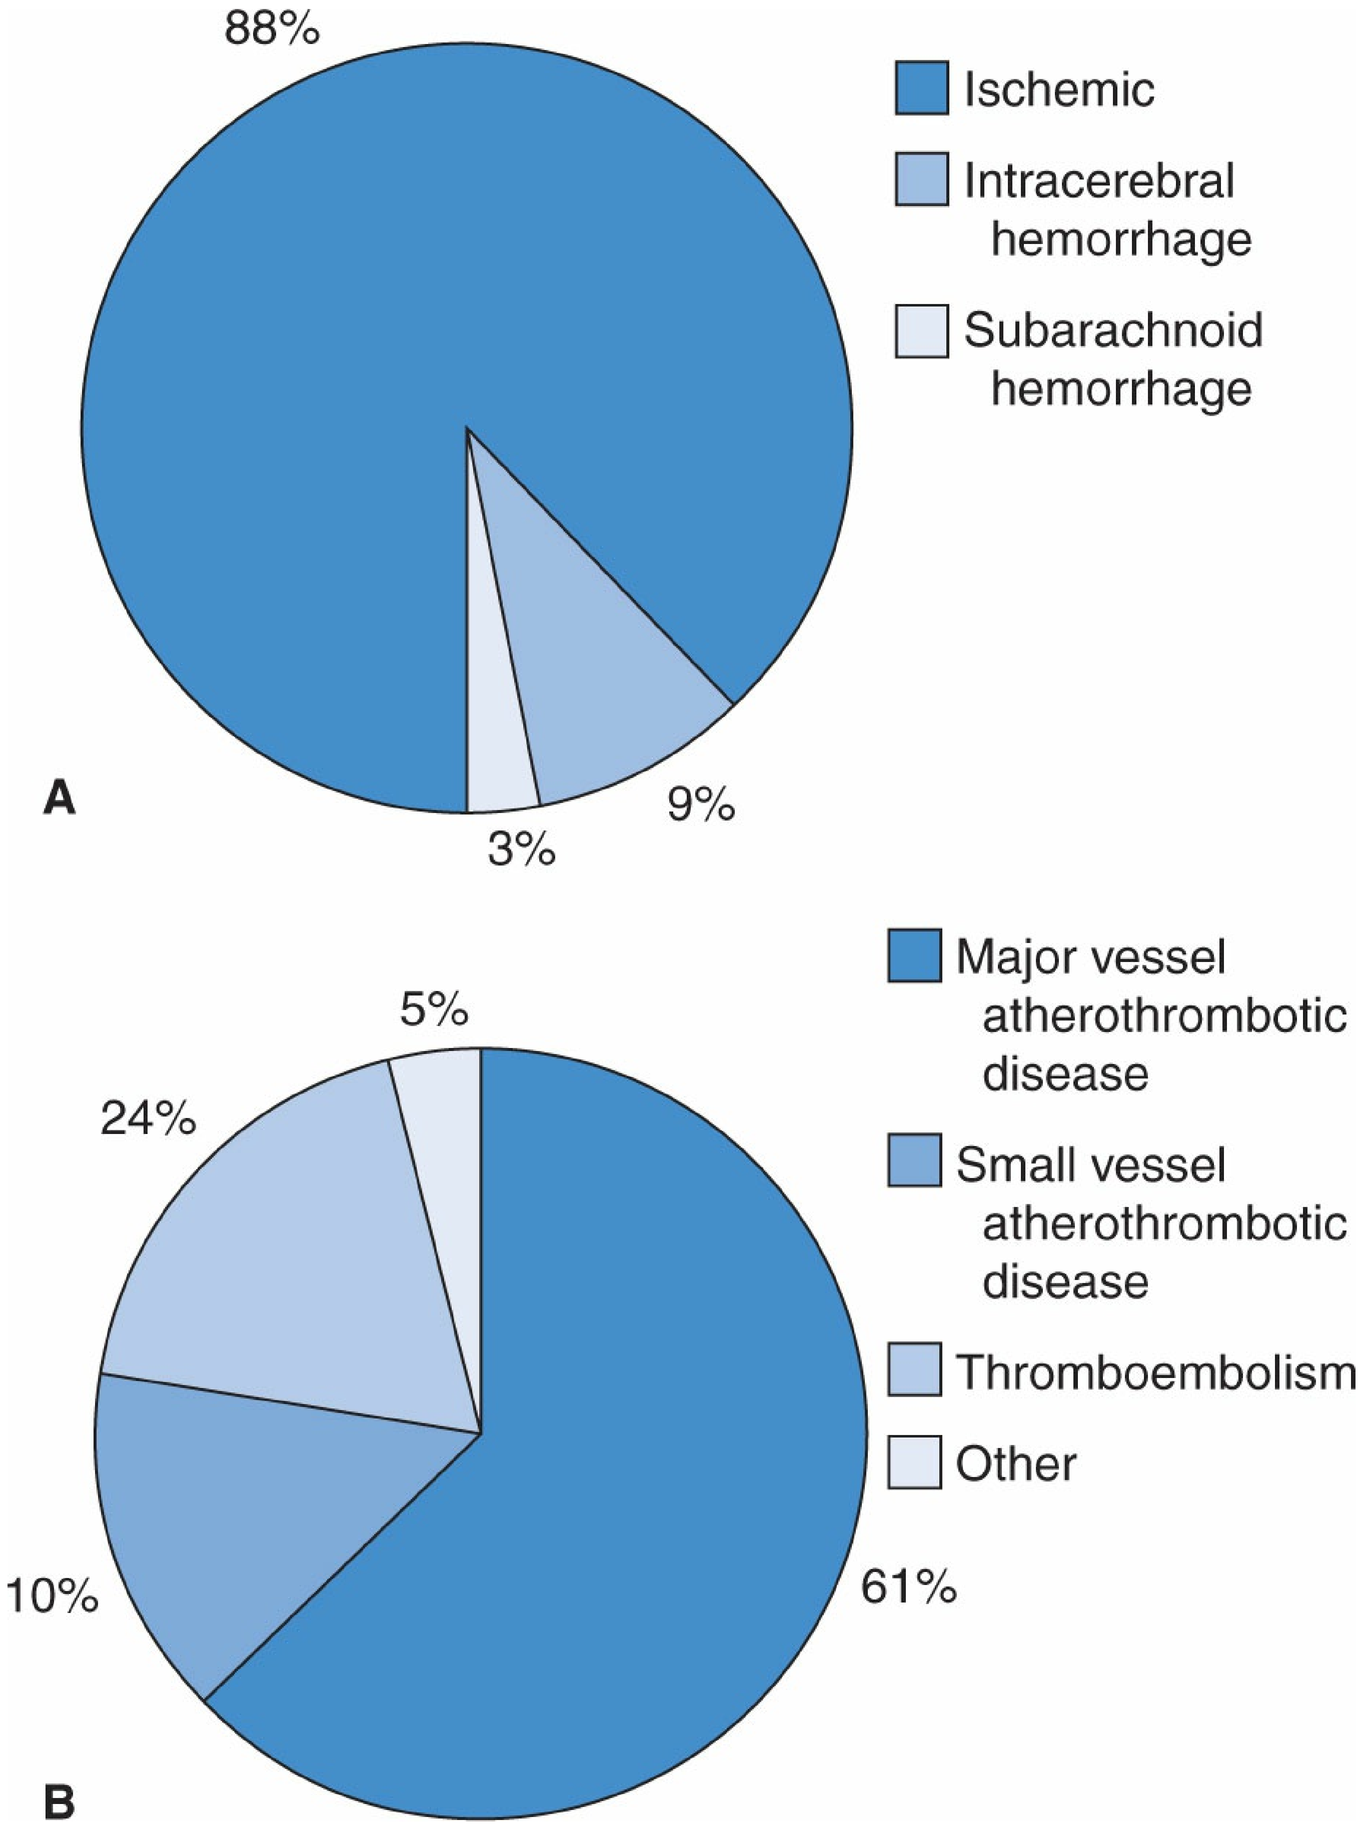

Figure 61-1 Etiology of strokes. Causes of all strokes.

Table 61-1

Risk Factors for Transient Ischemic Attack and Ischemic Stroke

Modifiable	Potentially Modifiable	Non-modifiable
Cardiovascular disease (coronary heart disease, heart failure, peripheral arterial disease) Hypertension Cigarette smoking Diabetes Asymptomatic carotid stenosis Atrial fibrillation Sickle cell disease	Metabolic syndrome Alcohol abuse (≥5 drinks daily) Hyperhomocysteinemia Drug abuse (e.g., cocaine, amphetamine, methamphetamine) Hypercoagulability (e.g., anticardiolipin, factor V Leiden, protein C deficiency, protein S deficiency, antithrombin III deficiency)	Age (doubling each 10 years after age 55) Race (blacks > Hispanics > whites) Sex (men > women) Low birth weight (<2,500 g) Family history of stroke (paternal > maternal)
Dyslipidemia (high total cholesterol, low HDL)	Oral contraceptive use (women 25–44 years old)	
Dietary factors (sodium intake <2,300 mg/day; potassium intake <4,700 mg/day)	Inflammatory processes (e.g., periodontal disease, cytomegalovirus, Helicobacter pylori seropositive)	
Obesity Physical inactivity	Acute infection (e.g., respiratory infection, urinary tract infection)	
Postmenopausal hormone therapy (women 50–74 years old)	CD40 ligand >3.71 ng/mL in women free of cardiovascular disease	
	IL-18 upper tertile	
	hs-CRP >3 mg/L in women 45 years or older	
	Migraine headaches	
	High Lp(a)	
	High Lp-PLA$_2$	
	Sleep-disordered breathing	

HDL, high-density lipoprotein; hs-CRP, high-sensitivity C-reactive protein; IL, interleukin; Lp(a), lipoprotein(a); Lp-LPA$_2$, lipoprotein-associated phospholipase A$_2$.

Source: Meschia JF et al. Guidelines for the primary prevention of stroke: a statement for healthcare professionals from the American Heart Association/American Stroke Association. Stroke. 2014;45:3754.

There is a strong relationship between the occurrence of TIA and an increased risk for subsequent cerebral infarction.[1],[2] The risk of an ischemic stroke is highest in the first 30 days after a TIA, and the risk within 90 days of a TIA is 3% to 17.3%. Additionally, nearly 25% of patients who experience a TIA will die within a year.[2] Risk factors for cerebral infarction are listed in Table 61-1. Risk factors for stroke are classified as either non-modifiable (e.g., age, race, gender) and modifiable if they can be altered (e.g., hypertension, high cholesterol level, smoking). Cerebral infarct prevention efforts will be focused on elimination and control of the modifiable risk factors.[4],[5] The control of risk factors is of primary importance in managing a patient with a TIA or cerebral infarction.

Intracerebral hemorrhages account for 10% of all strokes in North America, while subarachnoid hemorrhage, most commonly resulting from cerebral artery aneurysms, comprises 3% of all strokes. Hypertensive hemorrhage is the most common cause of ICH, with 46% of ICHs resulting from hypertension. In fact, hypertension more than doubles the risk of ICH. A number of medications including warfarin and other anticoagulants, such as dabigatran, rivaroxaban, and apixaban, significantly predispose patients to ICH. Less commonly, ICH may occur because of an arteriovenous malformation (AVM), which is a clump of arteries and veins that are intertwined, resulting in weakened blood vessel walls.

Pathophysiology

The neurologic sequelae of cerebral ischemia or infarction directly result from an embolic or thrombotic source. A clot may form in the heart, along the wall of a major blood vessel (e.g., aorta, carotid, or basilar artery), or in small arteries penetrating deep into the brain. If the clot is located near the infarction, it is a thrombus; however, when the clot has migrated to the brain from a distant source, it is an embolus. Either can diminish or block blood flow to the affected area of the brain. Disorders such as atrial fibrillation, mitral or aortic valve disease, patent foramen ovale, or coagulopathies are associated with formation of clots that may embolize to the brain.

Inflammatory mechanisms also contribute to the development of ischemia, especially thrombotic lesions. Substances, such as C-reactive protein, a mediator of inflammation, are elevated in patients with an acute stroke. Inflammation is thought to enhance the development of thrombotic lesions and result in sudden, intermittent occlusion of blood vessels. Disorders such as arteritis (Takayasu, Giant cell), and Moyamoya syndrome are examples of diseases where inflammation plays an important role for the development of brain ischemia.

Cerebral blood flow in the normal adult brain is 30 to 70 mL/100 g of brain tissue/minute. When a thrombotic or embolic clot partially occludes a cerebral artery, causing a reduction in blood flow to less than 20 mL/100 g/minute, various compensatory mechanisms are activated. These include vasodilation and increased oxygen extraction. If the artery is further occluded and cerebral blood flow is reduced to less than 12 mL/100 g/minute, the affected neurons become sufficiently anoxic to die within minutes (Fig. 61-2).[6] Rapid reestablishment of blood flow to the ischemic area can delay, prevent, or limit the onset of infarction, improving the outcome of the acute stroke.

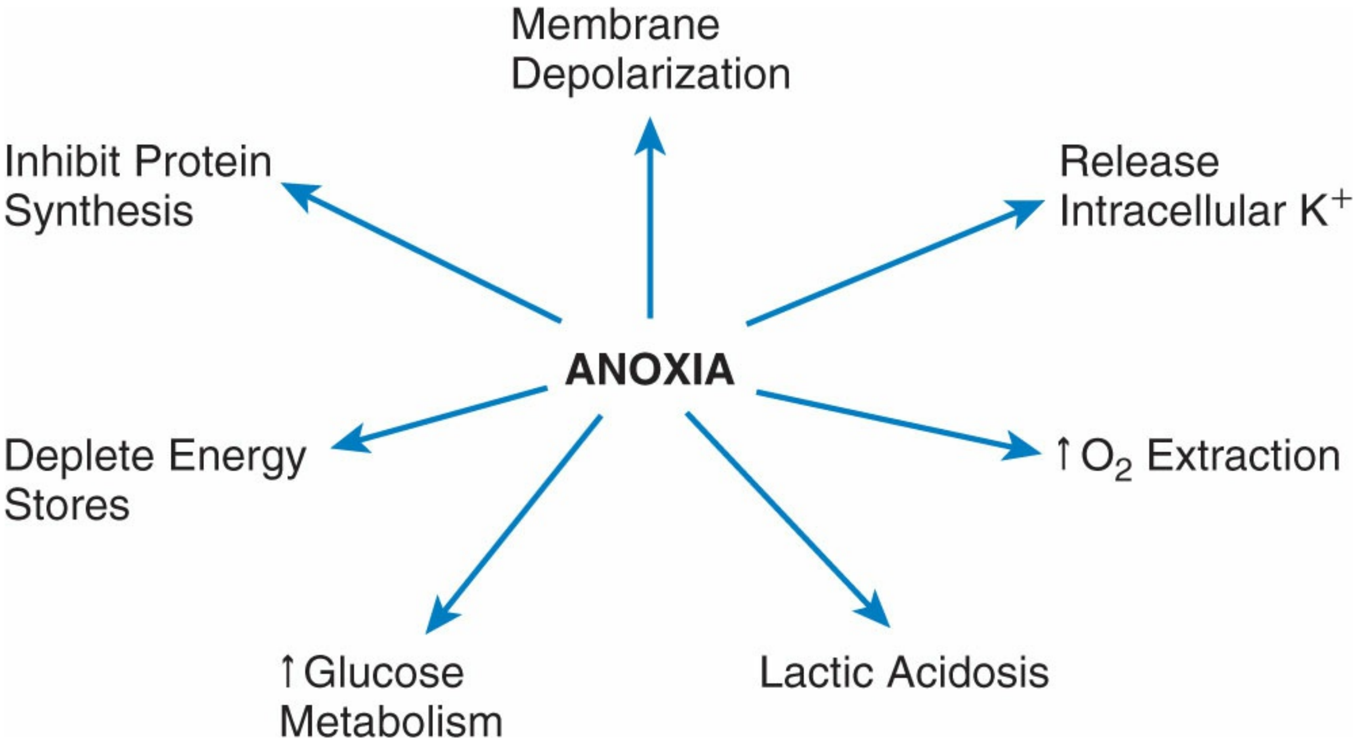

Figure 61-2 Physiologic effects of cerebral anoxia.

Ischemia in the brain usually involves a core or focal region of profound ischemia that results in neuronal death. The extent of this region is dependent on the amount of brain that is perfused directly by the blood vessel that becomes occluded. There is a surrounding area of brain that becomes marginally ischemic with normal function being disrupted. This region of marginal ischemia is frequently called the ischemic penumbra. If ischemia continues, neurons in this region will die. However, if normal blood flow is restored quickly, neurons in this area will survive.

When neurons become ischemic, excitatory neurotransmitters are released, causing neurons to rapidly and repeatedly discharge. Increased neuronal activity results in extreme metabolic demands, disrupts neuronal homeostasis, depletes stores of adenosine triphosphate, and synergistically increases the effects of hypoxia. Especially vulnerable to ischemic effects are neurons in the middle layers of the cerebral cortex; portions of the hippocampus (CA1 and subiculum regions), a structure running parallel to the parahippocampal gyrus; and Purkinje cells in the cerebellum.[7] There is also a rapid intracellular influx of calcium. Both voltage-dependent and chemical-dependent calcium channels are unable to act as a gate to prevent the movement of calcium, owing to depletion of cellular energy sources. Intracellular stores of calcium ions also are disrupted, causing release of calcium into the cytoplasm. Increased concentration of calcium ions enhances phospholipase and protease activity and increases reactive metabolites, such as superoxide and hydroxide ions, and nitric oxide. This eventually causes neuronal death.[6],[7] In addition, lipolysis of cell membranes occurs in the presence of an accumulation of neurotoxic free radicals.

Immediate therapeutic intervention is needed to limit and prevent permanent neurologic damage from these rapidly occurring events.

INTRACRANIAL HEMORRHAGE

Intracranial hemorrhages occur because of weakened intracranial blood vessels, elevated pressure inside the blood vessels, and anatomical abnormalities. Specific causes include hypertension, cerebral amyloid angiopathy, brain tumors, anatomical derangements such as AVMs, coagulopathies, and trauma. Pathophysiologic mechanisms differ depending on whether the bleeding occurs outside the brain parenchyma in the subarachnoid, epidural, or subdural space or within the intracerebral space.

In subarachnoid hemorrhage, blood moves quickly into the cerebrospinal fluid (CSF), causing an acute elevation of intracranial pressure (ICP). ICP refers to the pressure inside the intracranial vault and may be elevated because of brain tissue swelling, the development of a hematoma (collection of blood) inside the brain, or other conditions. Blood may also migrate into the intraventricular space or into the brain tissue.[8],[9] Obstruction of CSF fluid reabsorption and movement out of the brain because of the presence of blood in the brain can result in hydrocephalus, which is the buildup of CSF within the ventricles of the brain. Delayed cerebral ischemia, commonly referred to as "vasospasm" of the cerebral vasculature, may also complicate subarachnoid hemorrhage.

Epidural and subdural hematomas are other types of intracranial hemorrhages that occur outside the brain parenchyma. Depending on their size, epidural and subdural hematomas may significantly compress and displace brain tissue, resulting in elevated ICP and brain herniation because of mass effect. Brain herniation refers to abnormal movement of brain tissue across structures inside the skull that occurs because of elevated pressures within the intracranial vault. This squeezing of brain tissue can significantly compress cerebral blood flow, consequently compromising oxygen delivery to the brain and causing brain cells to die.

Spontaneous intracerebral hemorrhage because of hypertension develops in areas of the brain where smaller blood vessels branch out from large blood vessels at 90 degree angles, exposing the smaller vessels to the higher pressure of the preceding blood vessel and eventually resulting in bleeding of the smaller vessels.[10] In intracerebral hemorrhage, the movement of blood from blood vessels into the brain parenchyma causes local irritation of the brain tissue and edema. In the case of large hemorrhages and significant edema, mass effect can ultimately increase ICP, reducing blood flow to the brain and potentially causing brain tissue herniation.[11] Secondary brain injury occurs in many patients after spontaneous ICH. It is caused by a disrupted blood–brain barrier, release of inflammatory mediators, and progressive edema that may last 7 to 12 days.[12–15]

In spontaneous intracerebral hemorrhage, hematoma enlargement is associated with poor outcomes. Non-modifiable risk factors for hematoma expansion are large hematoma size and contrast extravasation on computed tomography (CT) at the time of presentation, while potentially modifiable risk factors include coagulopathies and ongoing uncontrolled hypertension after hospital admission.[16],[17]

General Treatment Principles

Rapid recognition of stroke symptoms and immediate initiation of treatment are essential to the management of ischemic or hemorrhagic stroke. Appropriate pharmacotherapy of stroke requires a precise diagnosis. It is vital to differentiate between an ischemic stroke and a hemorrhagic stroke, because an inaccurate diagnosis can lead to the use of drugs that may cause severe morbidity or mortality. Interventions to prevent and treat ischemic strokes are directed at reducing risk factors, eliminating or modifying the underlying pathologic process, and reducing secondary brain damage. In hemorrhagic stroke, the emphasis of treatment is on preventing hematoma expansion, managing intracranial pressure, and providing supportive therapy to maximize neurologic function and minimize complications. Rehabilitation is a key component of long-term care for many patients, regardless of whether the stroke is ischemic or hemorrhagic.

PRIMARY PREVENTION OF ISCHEMIC STROKE AND TRANSIENT ISCHEMIC ATTACKS

Risk Factors Modification

CASE 61-1

QUESTION 1: R.B. is a 60-year-old, 5 feet 6 inches tall, 85-kg woman who is concerned about having a stroke. Her father died of a stroke, and her 85-year-old mother has had several episodes diagnosed as TIAs. R.B.'s blood pressure is 140 to 150/90 to 100 mm Hg, and she was recently diagnosed with diabetes mellitus. She does not have a history of TIA or stroke. Additionally, she smoked for 25 years but has not used tobacco for the past 10 years. Her current medications include lisinopril, metformin, conjugated estrogen/medroxyprogesterone, and acetaminophen. She approaches her pharmacist because of concerns about having a stroke and being "like her parents." What can R.B. do to reduce her risk of stroke?

Any plan for primary prevention (i.e., prevention of a first event) of TIA or stroke must address the control or reduction of risk factors (Table 61-2).The reader is referred to a detailed discussion of treatment of diseases such as hypertension, diabetes, coronary artery disease, chronic kidney disease, etc. in their respective chapters (see Chapters 9, 13, 28, 53).

For R.B., hypertension is the most important and well-documented risk factor that requires immediate attention.[4] Adequate control of her blood pressure should reduce R.B.'s risk of stroke by 35% to 44%. On the basis of the eighth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High

Blood Pressure (JNC-8) guidelines, R.B.'s blood pressure goal should be less than 140/90 mm Hg.[18] Antihypertensives that have been associated with a stroke reduction risk are the angiotension converting enzyme inhibitor (ACE-I), hydrochlorothiazide, and calcium-channel blockers.[19] Because she is already receiving lisinopril and her blood pressure is poorly controlled, it is likely that a combination therapy is needed. The addition of hydrochlorothiazide 25 mg/day is advisable to R.B.[4]

Diabetes is another important risk factor for in RB. In older women, diabetes is a more significant risk factor for stroke than it is for men.[20] There is controversy regarding the intensity of glucose control that optimally reduces stroke risk. Clearly, good control of diabetes results in better control of hypertension and other risk factors for stroke.[21] Additionally, use of oral hypoglycemics may reduce the risk of stroke through mechanisms other than glycemic control. However, strict control of blood glucose did not reduce the risk of stroke over the course of 9 years in one study.[21] There is evidence that angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) reduce the risk of stroke in diabetics, with or without hypertension.[22],[23] For diabetic patients with at least one additional risk factor for cardiovascular disease, taking a β-hydroxy-β-methylglutaryl-CoA (HMG-CoA) reductase inhibitor appears to reduce the risk of stroke by approximately 24% even in the absence of hypercholesterolemia.[24],[25] It is known that HMG-CoA reductase inhibitors have anti-inflammatory activity that may influence the development of atherosclerotic plaques and cerebral ischemic processes.[26–28] Because of these effects of HMG-CoA reductase inhibitors, these drugs should be started for primary prevention of ischemic stroke and TIA even in patients who do not have dyslipidemia if the estimated 10-year risk of cardiovascular events is high, as recommended in the 2013 "ACC/AHA guideline."[4]

Table 61-2

Primary Prevention of Ischemic Stroke

Factor	Goal	Recommendation
Hypertension	Blood pressure <140/90 mm Hg	Follow JNC-8 guidelines; after lifestyle modification thiazide-type diuretic, angiotensin-converting enzyme inhibitor, or angiotensin receptor blocker, CCB (full discussion in Chapter 9, Essential Hypertension)
Atrial fibrillation	When warfarin is used, INR 2–3	Aspirin 75–325 mg/day or warfarin, rivaroxaban, dabigatran, apixaban, or edoxaban as determined by the use of the $CHADS_2$ or CHA2DSC2-VASC score (full discussion in Chapter 15, Cardiac Arrhythmias)

Dyslipidemia	National Cholesterol Education Program III goals	Lifestyle modification, HMG-CoA reductase inhibitor (full discussion in Chapter 8, Dyslipidemias)
Women (>65 years, history of hypertension, hyperlipidemia, diabetes, or 10-year cardiovascular risk ≥10%)	Reduce risk without bleeding complications	Aspirin 75–325 mg/day; use the lowest possible dose
Cigarette smoke	Elimination of cigarette smoke	Smoking cessation; avoidance of environmental tobacco smoke
Physical inactivity	≥30 minutes daily of moderate-intensity activity	Establish exercise program of aerobic activity
Excessive alcohol intake	Moderation	≤2 drinks/day for men or ≤1 drink/day for nonpregnant women
Diet and nutrition	≤2.3 g/day of sodium; ≥4.7 g/day of potassium	Institute a diet that is high in fruits and vegetables and low in saturated fats
Elevated lipoprotein(a)	Reduction of lipoprotein(a) by ≥25%	Niacin 2,000 mg/day as tolerated

HMG-CoA, β-hydroxy-β-methylglutaryl-CoA; INR, international normalized ratio; JNC-8, Eighth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure.

Source: Meschia JF, et al. Guidelines for the primary prevention of stroke: a statement for healthcare professionals from the American Heart Association/American Stroke Association. Stroke. 2014;45:3754–3832

Niacin, fibric acid derivatives, ezetimibe, or bile acid sequestrants can be considered for patients who do not tolerate HMG-CoA reductase inhibitors or have low high-density lipoprotein cholesterol concentrations; however, their efficacy in preventing a stroke is not established. The benefits of HMG-CoA reductase inhibitors appear to be a class effect, so selection of a specific agent should be based on the individual characteristics of the patient. For R.B., she should maintain tight control of her diabetes, continue her lisinopril, and start an HMG-CoA reductase inhibitor, such as simvastatin or atorvastatin.

The body mass index for R.B. is 30.2 kg/m^2, placing her in the obese category. Multiple large studies have demonstrated a direct relationship between increased body weight and an increased risk of stroke.[29],[30] There are no data available to establish the precise effect of weight reduction on reducing the risk of stroke. However, increasing physical activity and proper nutrition are essential to achieve weight loss and improve diabetes and blood pressure control.[31]

A diet high in sodium is associated with an increased risk in stroke, whereas a diet high in potassium appears to reduce the risk of stroke.[32],[33] Current recommendations for diet are for sodium intake of 2.3 g/day or less and potassium intake of at least 4.7 g/day.[4] In addition, a DASH-style diet, which emphasizes fruits, vegetables, and low-fat dairy products and reduced saturated fat is recommended to lower blood pressure and thereby reduce the risk of stroke.

Regarding physical activity, several studies have shown an inverse relationship between physical activity and risk of stroke.[34],[35] Therefore, at least 40 minutes/day of moderate-intensity exercise is recommended three to four times/week.[4] Cigarette smoking is an independent risk factor for stroke and potentiates other risk factors. In addition to active smoking, passive inhalation of cigarette smoke also appears to be a risk factor for stroke.[36] Smoking cessation does result in a rapid reduction in the risk of stroke, but the risk never returns to levels seen in individuals who have never smoked.[37]

Finally, five studies have specifically investigated the effect of hormone replacement on stroke risk.[38–42] On the basis of the results from these studies, R.B. should discontinue her conjugated estrogen/medroxyprogesterone product unless she is taking this medication for a specific reason other than control of menopausal symptoms or prevention of cardiovascular events. R.B. should be encouraged to avoid passive smoke and to continue avoiding the use of tobacco. R.B. should initiate a weight-reduction program that includes a low-sodium and high-potassium diet with an exercise program.

Pharmacotherapy Primary Prevention of Ischemic Stroke and Transient Ischemic Attacks

CASE 61-1, QUESTION 2: Would R.B. benefit from any antiplatelet or anticoagulation for the primary prevention of ischemic stroke and TIAs?

Aspirin has been carefully investigated for primary prevention of stroke. Although aspirin is recommended in the primary prevention of coronary heart disease, it is not generally recommended for the primary prevention of stroke or TIA in low-risk patients (10-year risk<10%).[4] In high-risk patients (>10-year risk >10%), the use of aspirin for cardiovascular (including but not specific to stroke) prophylaxis is reasonable. A patient's 10-year risk can be calculated using online calculators such as **http://my.americanheart.org/cvriskcalculator**.

In a study of 22,071 male physicians who took 325 mg of aspirin or placebo every other day for 5 years, stroke incidence was similar between groups. In addition, there was an increased risk of cerebrovascular events caused by hemorrhage in the aspirin group. Chen et al. reported a meta-analysis of 40,000 patients randomly assigned to aspirin and found a reduction from 47% to 45.8% in death and disability attributable to stroke.[44] Another study considered the role of aspirin for primary stroke prevention in women.[45] Women who took one to six tablets of aspirin per week had a slightly reduced risk of stroke and a lower risk of large-artery occlusive disease (relative risk, 59%; 95% confidence level, 0.29–0.85; $p = 0.01$). An increased risk of stroke was seen in women who took more than 7 aspirin weekly, and an excess risk of subarachnoid hemorrhage was seen in those taking more than 15 aspirin a week. The Women's Health Study also investigated the use of 100 mg/day in asymptomatic women and followed them for 10 years, monitoring for nonfatal cardiovascular events including stroke.[46] In this study, there was a 17% reduction in the risk for all strokes and a 24% reduction in the risk for ischemic stroke, whereas there was a nonsignificant increase in the risk for hemorrhage. Women 65 years of age and older at entry into the trial showed the most consistent risk reduction, but hemorrhagic strokes negated some of the benefit. Additionally, women with a history of hypertension, hyperlipidemia, or diabetes, or a 10-year cardiovascular risk of at least 10% had the most benefit. There are very limited data currently available regarding the use of other antiplatelet drugs for primary prevention of stroke except for cilostazol in patients with peripheral artery disease.[4]

Although oral anticoagulants are not generally considered safe for primary prevention of non-cardioembolic, patients with atrial fibrillation are candidates for primary prevention. These individuals are at risk for an embolic event arising from clot formation in the atrium of the heart. The CHADS2 score has been a widely used system of stratifying the risk of thromboembolism in non-valvular atrial fibrillation for a decade. It is generally accepted that low-risk patients (CHADS2 score = 0) should not be treated with anticoagulants but may be considered for antiplatelet therapy, while higher-risk patients (CHADS2 score ≥2) should be anticoagulated with oral anticoagulants such as warfarin, dabigatran, apixaban, rivaroxaban, or edoxaban (detailed discussion is available in Chapter 15, Cardiac Arrhythmias). The tool recommended in the new guidelines, called "CHA_2DS_2-VASc," also considers whether a patient has had prior vascular disease, evaluates people at younger ages (between 65–74) and factors in gender.[47] This is important because women face higher stroke risks. CHA_2DS_2-VASC score of ≥2 warrant the use of anticoagulants as first-line option. Numerous studies have clearly shown that warfarin prevents embolic cerebrovascular events for patients with valvular and non-valvular atrial fibrillation.[48–51] In these studies, the warfarin dose was adjusted to maintain an international normalized ratio (INR) of 1.5 to 4.5, with most recommendations to adjust the dose for an INR of 2 to 3. The selection of the antithrombotic agent depends on various factors including patient factors (risk of falls and hemorrhagic events), cost, age of the patient, tolerability, patient preference, and potential drug interactions. The Stroke Prevention in Atrial Fibrillation (SPAF) trial included aspirin combined with warfarin in one study arm and indicated that some benefit may be derived by combining antiplatelet agents with anticoagulants.[52] A follow-up study was performed and showed no difference between warfarin and aspirin in preventing stroke in atrial fibrillation.[51] In patients with non-valvular atrial fibrillation, aspirin can be used as an alternative to warfarin in patients with atrial fibrillation, based on the CHADS_2 score or CHA_2DS_2-VASC score (Table 61-3).[5],[47] Additionally, warfarin may be used in primary prevention of embolic stroke because of a patent foramen ovale.[5]

Table 61-3

CHADS$_2$ and CHA2DS2—VASC Score: Primary Stroke Prevention in Atrial Fibrillation

CHADS2 score	**CHAD2DS2—VASC score**
Add points for the following items. If score is <2, aspirin can be considered. If score is ≥2, anticoagulants (warfarin, apixaban, rivoraxaban, edoxaban) are recommended.	
Congestive heart failure = 1 point	Congestive heart failure = 1 point
Hypertension = 1 point	Hypertension = 1 point
Age >75 years = 1 point	Age >75 years = 2 points
Diabetes mellitus = 1 point	Diabetes mellitus = 1 point
Prior stroke or TIA = 2 points	Prior stroke or TIA = 2 points
	Vascular disease (e.g., peripheral artery disease, myocardial infarction, aortic plaque) = 1 point
	Age 65–74 years = 1 point
	Sex category (i.e., female) = 1point

TIA, transient ischemic attack.

Source: January C et al. 2014 AHA/ACC/HRS Guideline for the management of patients with atrial fibrillation: a report of the American College of Cardiology/American Heart Association Task Force on practice guidelines and the Heart Rhythm Society. Circulation. 2014;130:23.e199–e267.

For R.B., primary prevention of stroke with aspirin 81 mg/day can be considered because of her history of hypertension and diabetes. Given that she has no atrial fibrillation, she is not a candidate for anticoagulation therapy (see Table 61-4).

TREATMENT OF ACUTE ISCHEMIC STROKE AND TIA

Goals of Therapy

The immediate goal is to reestablish adequate blood flow in the diseased cerebral vessels, minimize brain injury, and treat medical complications. Longer-range objectives are to prevent reocclusion and decrease the risk of a future ischemic stroke.

Early Management of Acute Ischemic Stroke

CLINICAL PRESENTATION AND DIAGNOSTIC TESTS

CASE 61-2

QUESTION 1: P.C., a 65-year-old man (100 kg, 5 feet 9 inches), is admitted through the emergency department (ED) with right-sided weakness. As per report the patient was last seen well around 8:30 PM by his wife. Around 9:15 PM, the patient's son heard a bump and went upstairs to find his father on the floor. The patient had a slurred speech and had a right facial droop. At this point 911 was called and patient arrived at 9:45 PM to ED. He regained consciousness by the time he arrived in the ED. Both right extremities are flaccid. He is unable to speak but is capable of understanding instructions (i.e., expressive aphasia). Gross ophthalmologic examination indicates right-sided neglect (inability of his eyes to track to the right or acknowledge the right side of his body). His blood pressure is 165/95 mm Hg; other vital signs are normal. Laboratory studies are all within normal limits. What interventions should have been initiated before arrival in the ED?

Table 61-4

Drugs for Preventing Transient Ischemic Attacks and Ischemic Stroke

Drug	Action	Dose	Adverse Effects
Aspirin	Antiplatelet	50–325 mg/day	Diarrhea, gastric ulcer, GI upset
Dipyridamole	Antiplatelet (use in combination with aspirin)	200 mg sustained-release twice daily With aspirin 50 mg BID	GI upset
Ticlopidine	Antiplatelet	500 mg/day	Diarrhea, neutropenia, rash
Clopidogrel	Antiplatelet	75 mg/day	Thrombocytopenia, neutropenia
Cilostazol	Antiplatelet	100 mg BID	Headache, peripheral edema. Contraindicated in congestive heart failure patients
Warfarin	Anticoagulant (only in patients with cardioembolic cause of stroke/TIA	Titrate to goal INR 2–3 for most patients 2.5–3.5 with mechanical valve	Bleeding, bruising, petechiae
Rivaroxaban	Anticoagulant (only in patients with cardioembolic cause of stroke/TIA	If CrCl >15 mL/minute, 20 mg once daily with evening meal	Bleeding
Apixaban	Anticoagulant (only in patients with cardioembolic cause of stroke/TIA	5 mg BID If Scr ≥1.5 mg/dL, 2.5 mg BID (if age >80 years or weight ≤60 kg)	Bleeding
Edoxaban	Anticoagulant (only in patients with cardioembolic cause of stroke/TIA	60 mg daily If CrCl 15–50 mL/minute 30 mg daily	Do not use if CrCl >95 mL/minute as high risk of ischemic stroke
Dabigatran	Anticoagulant (only in patients with cardioembolic cause of stroke/TIA	150 mg BID If CrCL 15–30 mL/minute: 75 mg BID	GI bleed

GI, gastrointestinal; INR, international normalized ratio; BID, 2 times daily; CrCl, creatinine clearance; TIA, transient ischemic attack; Scr, serum creatinine.

Immediate recognition of, and response to, stroke symptoms are essential to an optimal outcome. As soon as stroke symptoms are recognized, the emergency medical system should be activated. Emergency medical personnel should be trained to gather important historical information, especially when the symptoms started. This is defined as "when the patient was at his or her previous baseline or symptom-free state. For patients unable to provide information or who was awaken with stroke symptoms, the time of onset is defined as when the patient was last awake and symptom-free or known to be normal."[53] Use of a standardized evaluation tool such as the Cincinnati Prehospital Stroke Scale or Los Angeles Prehospital Stroke Screen is useful in distinguishing stroke symptoms from other disorders, such as conversion disorder, hypertensive encephalopathy, hypoglycemia, complicated migraine, or seizures.[53],[54]

General supportive care for respiratory and cardiovascular function should be initiated before transporting the patient to the ED. An important key to effectively managing acute stroke patients is to have a well-designed evaluation and treatment algorithm that addresses assessment and care of the patient from initial onset of symptoms through rehabilitation. Patients with suspected cerebral infarction should be transported, if possible, to the closest certified primary care center. A certified primary care center would have a multidisciplinary team and would be activated and notified by the emergency personnel while potential stroke patient is en route (Fig. 61-3).[53] If a primary stroke center is not locally available, patients can be stabilized in community hospital. In these situations, local providers may use practice arrangements with larger centers that allow the provision of advanced care under the supervision of experts at a primary stoke center.

CASE 61-2, QUESTION 2: What diagnostic tests and evaluations will be helpful in guiding P.C.'s therapy?

Basic laboratory and diagnostic tests should be quickly performed to exclude non-cerebrovascular causes of P.C.'s symptoms, such as metabolic or toxicologic derangement or infections. These tests include a routine serum chemistry profile (electrolytes, blood urea nitrogen, serum creatinine, hepatic enzymes, calcium, phosphorus, magnesium, albumin), complete blood count, and toxicology screen. Coagulation studies, including a prothrombin time with INR and partial thromboplastin time, should be performed to provide baseline values for potential anticoagulation or thrombolytic therapy. In addition, a thorough physical, neurologic, cardiovascular, and mental status examination should be performed. The neurologic examination will assist in localization of the lesion in the CNS. The physical examination should include use of the National Institutes of Health Stroke Scale.[54] In addition to providing important information for diagnosis of his neurologic compromise, these tests will provide baseline data for ongoing assessment of P.C.'s progress and recovery.

The etiology of a stroke (ischemic versus hemorrhagic) is difficult to discern based solely on a physical and neurologic examination. As a result, CT or magnetic resonance imaging (MRI) is valuable in the evaluation of these patients. An MRI is preferred to a CT because of its superior tissue contrast, ability to obtain images in multiple planes, absence of artifacts caused by bone, vascular imaging capabilities, absence of ionizing radiation, and safer contrast media. MRI also allows for a magnetic resonance angiogram to be performed, allowing visualization of the cerebro-vasculature and possible identification of the precise location of the thrombus or embolus. Within the first 24 hours of an ischemic stroke, an MRI is clearly more sensitive than a CT. After 48 hours, the MRI and CT are equally effective in detecting ischemic infarcts. The primary disadvantages of the MRI are that it is more sensitive to artifacts, more difficult to perform in unstable patients, and not always available in smaller hospitals or communities. In addition, MRI is also not safe to be done in patients who have metallic implants, or pacemakers.

P.C. must have either a CT or an MRI before initiation of any specific therapy for stroke. A follow-up CT or MRI in 5 to 7 days is useful to determine the extent of neurologic damage resulting from the ischemic stroke.

Angiographic, Doppler, or sonographic examination of the cerebral vasculature may be helpful in identifying the location of the vascular lesion. These tests usually are performed after the patient has been stabilized, unless angioplasty with stents, mechanical retrieval devices, or use of intra-arterial fibrinolytics is anticipated. A lumbar puncture with collection of CSF for evaluation may be helpful in identifying the presence of blood in the CNS. In the presence of suspected increased intracranial pressure, a lumbar puncture must be avoided because of the potential for tentorial herniation.

Treatment

CASE 61-2, QUESTION 3: A head CT revealed left MCA territory infarct with no cerebral hemorrhage or edema. Is PC a candidate for intravenous thrombolysis?

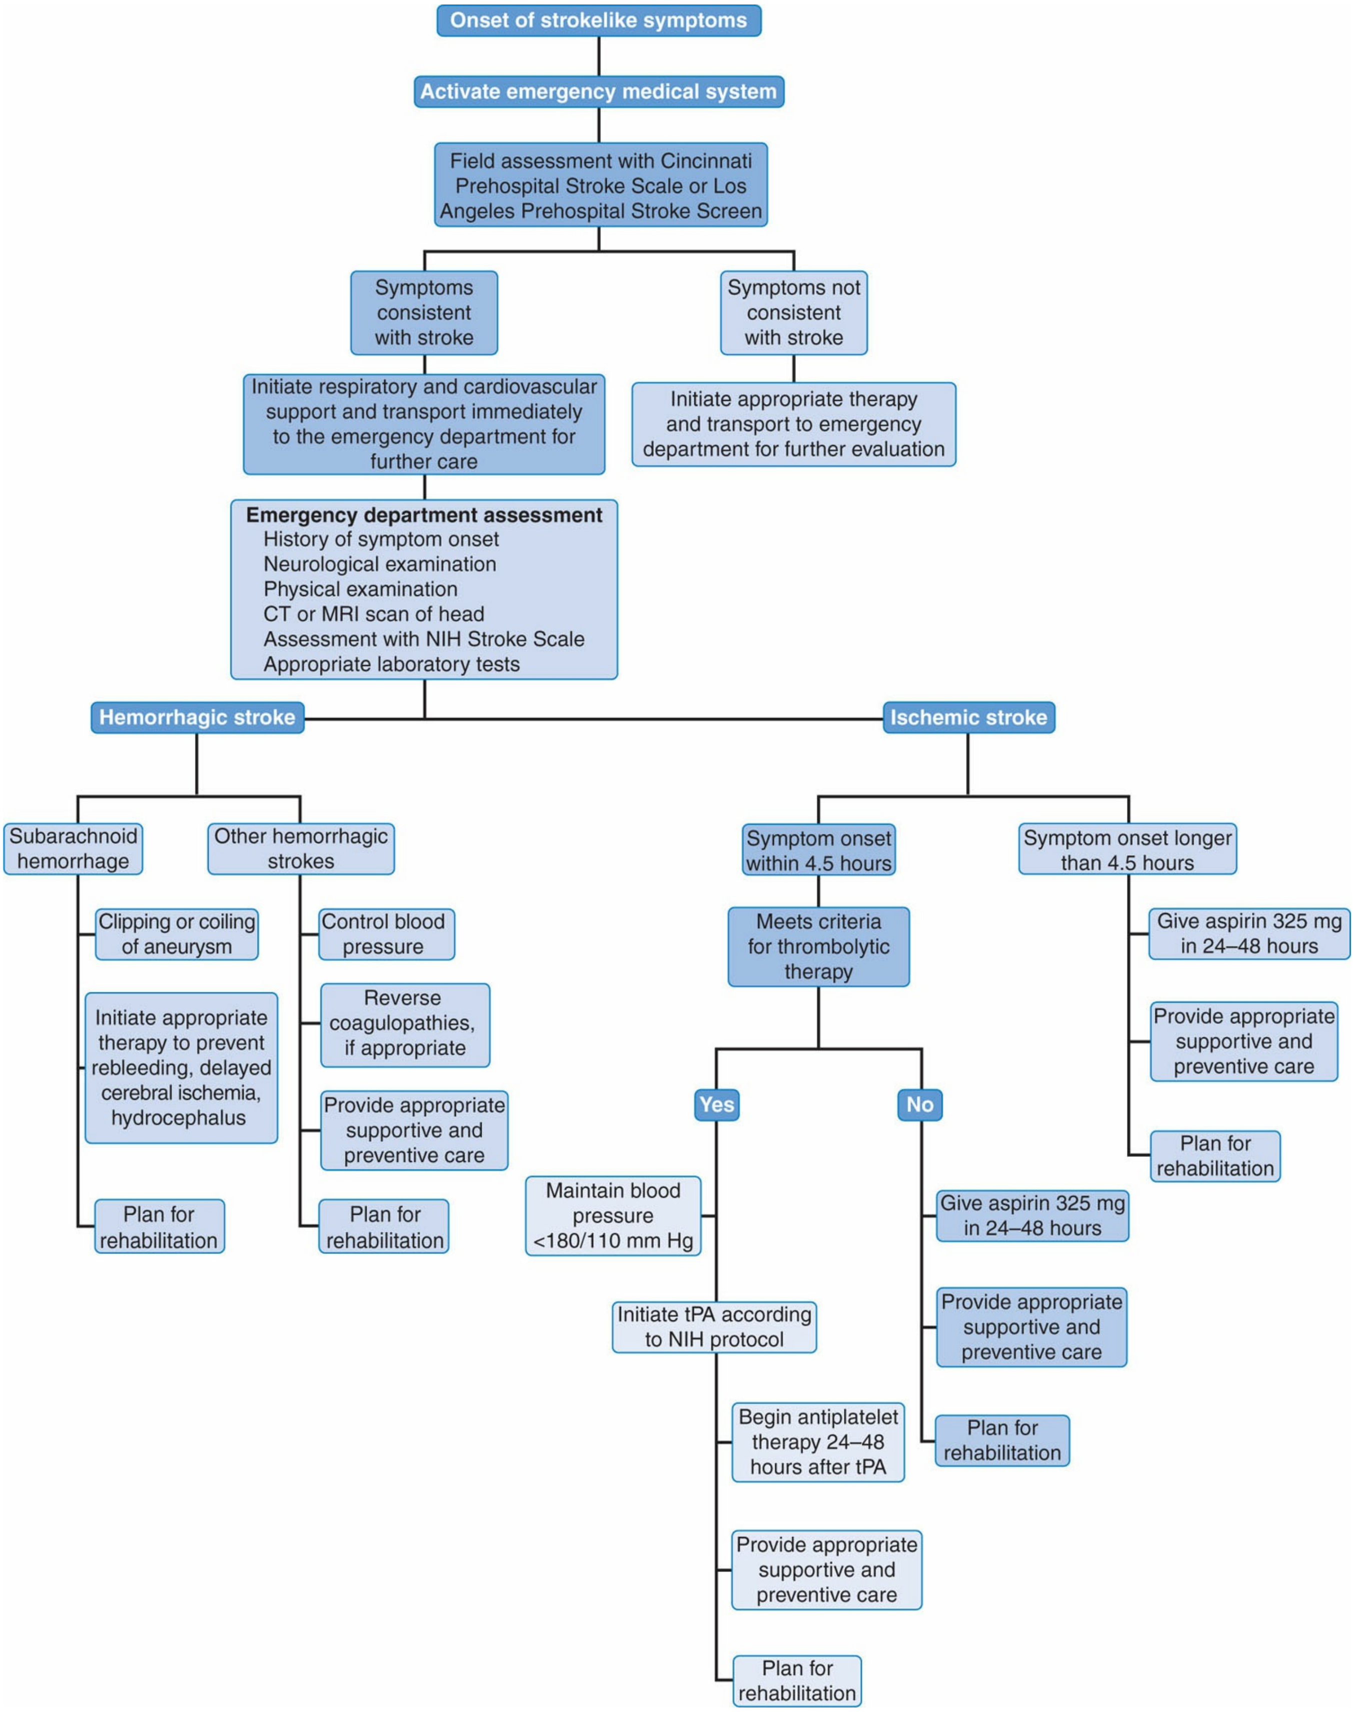
The critical primary event in a thromboembolic stroke is the development of an acute thrombus. Prospective cerebral angiography has demonstrated an arterial occlusion corresponding to the area of acute neurologic deficit in greater than 90% of cases.[55]

Occlusion of cerebral arteries does not cause complete ischemia because collateral circulation from other arterial sources provides unstable and incomplete circulation to the ischemic region of the brain.[56] When blood flow is sustained in the range of 10 to 18 mL/100 g/minute, irreversible cellular damage may occur. Blood flow must be restored quickly after the event. Experimental studies in dogs and cats have shown that when blood flow is restored within 2 to 3 hours, neurologic deficits are prevented.[57],[58] Thrombolytic agents can reestablish blood flow to ischemic regions of the brain. The most important factor in successful thrombolytic therapy is early treatment. The selection of appropriate candidates for thrombolysis is extremely important and requires the correct neurologic evaluation by a specialized team. Before the initiation of thrombolytics, patients with high blood pressure should have their blood pressure lowered carefully to systolic BP <185 and diastolic BP <110 mm Hg (see Table 61-5 and the discussion later on blood pressure).

Randomized, controlled-trials have shown that intravenous tissue plasminogen activator (tPA), alteplase, to be beneficial for select patients with acute ischemic stroke who start treatment within 4.5 hours. For eligible patients (Table 61-6), once a CT ruled out a hemorrhage, intravenous tPA should be started within 4.5 hours of clearly defined symptoms. There are specific criteria to select patients for alteplase eligibility if they present within 3 hours of onset of symptoms versus if they present up to 4.5 hours of symptoms (see Table 61-6).

Several thrombolytics (streptokinase, alteplase, tenectaplase, reteplase, urokinase) are available. However, only alteplase trials have shown benefits and improved outcomes.[59–62]

In three studies, streptokinase was used as the thrombolytic, and all of these studies were terminated early owing to high rates of mortality and intracranial hemorrhage associated with streptokinase.[59],[60],[63] The rates of intracranial hemorrhage ranged from 6% to 17% for patients receiving streptokinase compared with 0.6% to 3% for patients receiving placebo.



Onset of strokelike symptoms
Activate emergency medical system
Field assessment with Cincinnati Prehospital Stroke Scale or Los Angeles Prehospital Stroke Screen
Symptoms consistent with stroke
Symptoms not consistent with stroke
Initiate respiratory and cardiovascular support and transport immediately to the emergency department for further care
Initiate appropriate therapy and transport to emergency department for further evaluation
Emergency department assessment
History of symptom onset
Neurological examination
Physical examination
CT or MRI scan of head
Assessment with NIH Stroke Scale
Appropriate laboratory tests
Hemorrhagic stroke
Ischemic stroke
Subarachnoid hemorrhage
Other hemorrhagic strokes
Clipping or coiling of aneurysm
Initiate appropriate therapy to prevent rebleeding, delayed cerebral ischemia, hydrocephalus
Plan for rehabilitation
Control blood pressure
Reverse coagulopathies, if appropriate
Provide appropriate supportive and preventive care
Plan for rehabilitation
Symptom onset within 4.5 hours
Symptom onset longer than 4.5 hours
Meets criteria for thrombolytic therapy
Yes
No
Maintain blood pressure <180/110 mm Hg
Initiate tPA according to NIH protocol
Begin antiplatelet therapy 24–48 hours after tPA
Provide appropriate supportive and preventive care
Plan for rehabilitation
Give aspirin 325 mg in 24–48 hours
Provide appropriate supportive and preventive care
Plan for rehabilitation
Give aspirin 325 mg in 24–48 hours
Provide appropriate supportive and preventive care
Plan for rehabilitation

Figure 61-3 Treatment algorithm for management of patient with acute stroke-like symptoms. CT, computed tomography; MRI, magnetic resonance imaging; NIH, National Institutes of Health; t-PA, alteplase. (Source: Adams HP et al. Antifibrinolytic therapy in patients with aneurysmal subarachnoid hemorrhage: a report of the cooperative aneurysmal study. Arch Neurol. 1981;38:25.)

The National Institute of Neurological Disorders and Stroke (NINDS) alteplase trial[61] and the European Cooperative Acute Stroke Study (ECASS I)[62] used different doses, inclusion criteria, and treatment protocols. Both trials showed the benefit of alteplase in at least some outcome parameters. In the NINDS alteplase study, patients were enrolled within 3 hours of symptom onset using strict inclusion and exclusion criteria. When enrolled, patients received either alteplase 0.9 mg/kg (maximal dose, 90 mg), with 10% of the dose given as a bolus for 1 minute and the remainder infused for 60 minutes, or placebo. In this study, there were no differences at 24 hours in responses between the placebo group and those who received alteplase. However, at 3 months, patients who received alteplase were 30% more likely to have minimal or no disability. There was an 11% to 13% absolute increase in the number of patients with excellent outcomes and a corresponding decrease in the number of patients with severe neurologic impairment or death at 3 months. Intracranial hemorrhage occurred more frequently among patients receiving alteplase (6.4%) than in patients receiving placebo (0.6%). Despite the increased incidence of intracranial hemorrhage, outcomes remained better for patients receiving alteplase. For the ECASS I trial, patients were enrolled within 6 hours of the onset of symptoms.[62] The treatment protocol consisted of intravenous alteplase 1.1 mg/kg (maximal, 100 mg) or placebo. There was no difference in the primary outcome measures of functionality at 3 months. However, with target population analysis, there was a significant difference favoring alteplase. Of alteplase-treated patients, 41% had minimal or no disability compared with 29% of placebo-treated patients. A variety of secondary outcome measures favored alteplase. There was no difference in 30-day mortality rates, but 19.8% of alteplase-treated patients had major parenchymal hemorrhages compared with 6.5% of placebo-treated patients.

Table 61-5

Management Guideline for Blood Pressure Treatment in Acute Ischemic Stroke

Treatment	Received Alteplase	Did Not Receive Alteplase
No treatment recommended	If BP is <185/110 mm Hg	If BP <220/120 mm Hg unless there is another specific medical condition
Nicardipine 5 mg/hour, titrate up by 2.5 mg/hour every 5–15 minutes (maximum 15 mg/hour) Labetalol 10–20 mg IV over 1–2 minutes, may repeat to maximum of 300 mg total, or Labetalol 10 mg IV followed by continuous infusion 2–8 mg/minute	If BP >185/110 mm Hg Goal is to lower below 185/105 mm Hg to limit risk of ICH	If systolic BP >220 mm Hg or diastolic 120–140 mm Hg
IV sodium nitroprusside 0.5 mcg/kg/minute	If BP not controlled by above or if diastolic BP is >140 mm Hg	If not controlled or if diastolic BP >140 mm Hg

Table 61-6

Criteria for Alteplase Use in Treatment of Acute Stroke

Inclusion Criteria	Exclusion Criteria
18 years of age or older Clinical diagnosis of stroke with clinically meaningful neurologic deficit Clearly defined onset within 180 minutes before treatment Baseline CT with no evidence of intracranial hemorrhage	CT signs of intracranial hemorrhage, or multilobar infarction, or symptoms of subarachnoid hemorrhage Active internal bleeding History of intracranial hemorrhage Stroke or serious head injury within 3 months Current use of direct thrombin inhibitors or direct factor Xa inhibitors with elevated sensitive laboratory test Systolic BP >185 mm Hg, diastolic BP >110 mm Hg Current use of anticoagulant with INR >1.7 Current use if direct thrombin inhibitors with elevated sensitive laboratory tests (such as aPTT, INR, ECT, TT, and factor Xa activity assay) Heparin received in last 48 hours resulting in abnormal elevated aPTT Glucose <50 or 400 mg/dL Symptoms of subarachnoid hemorrhage Platelet count <100,000/mm^3 Relative exclusion criteria Only minor or rapidly improving stroke symptoms Pregnancy Seizure at onset with postictal residual neurologic impairments Major surgery or serious trauma within 2 weeks GI or urinary tract hemorrhage within 3 weeks
	Additional Relative Exclusion Criteria for Alteplase Use 3–4.5 hours after Onset of Symptoms
	Age >80 years NIHSS score >25 Taking an oral anticoagulant regardless of INR History of both diabetes and prior ischemic stroke

BP, blood pressure; CT, computed tomography; GI, gastrointestinal; NIHSS, National Institutes of Health Stroke Scale; ECT, ecarin clotting time; aPTT activated partial thromboplastin time; TT, thrombin time.

Since NINDS and ECASS-I, three subsequent trials, the ECASS-II and Alteplase Thrombolysis for Acute Non-Interventional Therapy in Ischemic stroke (ATLANTIS A and B) found largely same effects as NINDS when therapy was initiated in the

---

≤3-hour time period. The ECASS-II study used an alteplase dose of 0.9 mg/kg and replicated the NINDS trial[64]; however, patients were enrolled up to 6 hours after the onset of stroke symptoms. This study found no difference between alteplase and placebo. Too few patients were enrolled with stroke symptoms within 3 hours to reliably evaluate the influence of this variable on outcome.

Since NINDS, several trials have also investigated the use of intravenous alteplase up to 6 hours after stroke onset. ECASS-I, ECASS-II, ATLANTIS A and B, all enrolled patients with extended window use of alteplase. None of these trials found individually a benefit; however, a pooled analysis suggested improved outcomes.[65] Hence, the ECASS-III study was conducted to evaluate the efficacy and safety of alteplase administered used the NINDS alteplase dose (0.9mg/kg maximum of 90mg), but it focused on the efficacy and safety of alteplase administered 3 to 4.5 hours after the onset of symptoms.[66] A significantly greater number of patients receiving alteplase had favorable outcomes on the mRS global disability scale compared with placebo (odds ratio, 1.34; 95% confidence interval, 1.02–1.76). Although the rate of intracranial hemorrhage was greater with alteplase, mortality and reports of adverse events were similar between the two groups. When considering the use of alteplase in the 3- to 4.5-hour window, the ECASS-III criteria should be followed (Table 61-6). A second large randomized placebo-controlled trial was recently published. In this third International Stroke Trial (IST-3), following NINDS dosing scheme for alteplase, patients enrolled with 6 hours of symptoms onset, there was a significant improvement in functional outcome in the Oxford Handicap score (0 to 2, alive and independent) (OR 1.27; 95% confidence interval 1.10–1.47). There were more deaths at 7 days in the alteplase group though. ITS-3 included patients >80 years of age in comparison to ECASS-III and a broader blood pressure eligibility.[67] Because P.C. presented to the ED within 3 hours of the onset of his stroke symptoms, he is a candidate for alteplase therapy in accordance with the NINDS study protocol making sure the patient has no exclusion criteria based on Table 61-6.

CASE 61-2, QUESTION 4: What general treatment interventions should be made for P.C.?

In addition to the general supportive therapy needed for a hospitalized patient, several issues are important to the proper management of a stroke patient.

Assessing vital signs and ensuring stabilization of airway, breathing and circulation is the initial part of the evaluation. Intubation and mechanical ventilation may be required to ensure adequate ventilation and to protect the airways from aspiration. Careful attention should be given to fluid and electrolyte control. Excessive hydration or inadequate sodium supplementation may result in hyponatremia, potentially causing cerebral edema. This can result in compression and displacement of brain tissue which can disrupt cerebral perfusion. In addition, hyponatremia can produce seizures, which increases the metabolic demand on compromised neurons. Thus, 0.9% saline or lactated Ringer’s are the preferred fluids in patients at risk for cerebral edema.[53]

Attention to body temperature needs to be given. Studies have shown that even small increases in temperature are associated with worse outcomes after acute stroke.[68],[69] Hypothermia is neuroprotective, and a reduction in body temperature of 0.26°F can be beneficial in stroke patients.[53],[70] Use of antipyretics, such as acetaminophen, are advised to maintain normal or slightly subnormal body temperatures.

Another metabolic parameter that must be followed carefully is the serum glucose concentration, because hyperglycemia may adversely affect ischemic infarction outcomes. A review of multiple studies on the effects of hyperglycemia in acute stroke concluded that hyperglycemia results in poor outcomes and increased mortality.[71] If hyperglycemia is detected, appropriate insulin therapy should be initiated to keep the serum glucose concentration less than 140 mg/dL without causing hypoglycemia.[53]

Caution should be exercised in the acute management of P.C.'s blood pressure. Decreasing the blood pressure too rapidly will compromise cerebral blood flow and expand the region of ischemia and infarction, whereas hypertension may place him at a greater risk for cerebral hemorrhage, especially if a thrombolytic agent is used. However, a study comparing treated and untreated patients who were hypertensive in association with an acute stroke failed to demonstrate any difference in outcomes between the groups.[72]

For patients with a systolic blood pressure greater than 185 mm Hg or diastolic blood pressure greater than 110 mm Hg, who are otherwise candidates for intravenous fibrinolytic treatment, labetalol, nitroglycerin paste, or intravenous nicardipine should be used to reduce the blood pressure to these goals before starting alteplase.[53] A reasonable goal is to lower blood pressure by 15% during the first 24-hours after onset of stroke. After administration of alteplase, a systolic blood pressure should be kept less than 180/105 mm Hg to limit the risk of intracranial hemorrhage. Specific blood pressure management recommendations are outlined for the management of acute ischemic stroke patients (Table 61-5). In other patients, the only consensus on blood pressure control is that treatment is required when pressures exceed 220/120 mm Hg. If there is a clinical deterioration of neurologic function associated with the reduction of blood pressure, the infusion rate of the antihypertensive agent should be slowed or the drug discontinued. After the first 24 hours of stroke onset, maintenance antihypertensive therapy can then be initiated using an oral agent, such as a thiazide diuretics, calcium-channel antagonist or ACEI or ARB. The reader is referred to more detailed discussion of hypertension management in Chapter 9.

The general daily needs of the patient should be assessed and provided on an as-needed basis. These include nutrition, urination, defecation, delirium, and prevention of deep venous thrombosis, and decubitus ulcers. Neurologic deficits will compromise the ability of many patients to adequately meet these needs, increasing the necessity for medical assistance.

CASE 61-2, QUESTION 5: Should anticoagulation or antiplatelet agents be used acutely in P.C.?

Several studies have evaluated the use of anticoagulants in the treatment of acute strokes. However, most of these studies are poorly designed or underpowered to determine the efficacy of these agents.

HEPARIN AND HEPARINOIDS

Three studies have evaluated the use of heparin in acute stroke.[73–75] In one double-blind study, heparin doses were adjusted to maintain the partial thromboplastin time (aPTT) at 1.5 to 2 times control and continued for 7 days.[73] There were no significant differences in death at 7 days, no differences in functional ability 1 year after the stroke, and a greater mortality rate at 1 year for heparin-treated patients. Another study compared aspirin, subcutaneous heparin (5,000 international units or 12,500 international units BID), both, and neither treatments for patients with acute ischemic stroke.[74] There was no reduction of mortality or morbidity for patients receiving either dose of heparin. Heparin use has also been studied in progressing stroke (stroke with evolving neurologic symptoms), and no benefit was demonstrated with its use.[75] No studies have demonstrated that heparin is useful in mitigating the neurologic effects of a stroke.

Low-molecular-weight heparins (LMWHs) and heparinoids have been evaluated in several studies for acute stroke. Two doses of nadroparin were compared with placebo in one randomized, double-blind, placebo-controlled trial.[76] There were no differences in death rates or functional ability at 3 months among the three treatment arms. However, at 6 months, patients receiving high-dose nadroparin (i.e., 4,100 anti-Xa international units BID) had improved function. A large randomized, placebo-controlled trial of dose-adjusted danaparoid, a low-molecular-weight heparinoid, did not demonstrate improvement in danaparoid-treated patients.[77] In addition, no improvements were observed in studies of dalteparin and certoparin.[78],[79] Similar to heparin, LMWHs and heparinoids are not indicated in the acute treatment of stroke.

Deep vein thrombosis and pulmonary embolism are common complications in patients following a stroke. Intermittent Compression Devices such as Venodynes, which prevent pooling of blood in the lower extremities, should be applied within 24 hours of admission to the hospital unless contraindicated. The incidences of deep vein thrombosis and pulmonary embolism were reduced in most studies in which patients received heparin, LMWHs, or heparinoids.[80]

Unfractionated heparin 5,000 units subcutaneously twice daily or three times daily can be initiated in P.C. for deep venous thrombosis prophylaxis after 24 hours of thrombolytic administration once a repeat head CT ruled out ICH. Heparin is considered a cheap and effective option compared to LMWHs.

ANTIPLATELETS

Aspirin

One study evaluated early administration of aspirin in acute stroke. The Chinese Acute Stroke Trial compared 160 mg/day of aspirin administered within 48 hours of the onset of stroke symptoms with placebo.[81] Patients who received aspirin had reduced early mortality rates, but there was no difference in the primary endpoint of death or dependency at discharge from the hospital. Two other studies did not demonstrate benefit with aspirin.[63],[74] When data from these studies are combined, a slight beneficial effect of aspirin is seen with regard to reducing the risk of early stroke recurrence. Current recommendations are for aspirin 325 mg to be administered within 24 to 48 hours of the onset of stroke symptoms, except when alteplase is administered. When alteplase is given aspirin should be given 24 to 48 hours after alteplase administration but still within 48 to 72 hours of onset of stroke symptoms.[53] In our patient, P.C., alteplase was used, aspirin should not be given until 24 to 48 hours after the end of the alteplase infusion and once a repeat 24 hour head CT ruled ICH.

There has been limited published evidence available for the usage of other antiplatelets such as clopidogrel or dipyridamole in the acute treatment of ischemic stroke. Small pilot studies suggested some utility to these antiplatelets without providing solid evidence of a clear benefit of the well-established aspirin in acute ischemic stroke treatment. In the clopidogrel with aspirin in acute minor stroke or TIA (CHANCE), the investigators randomized in a double-blind, placebo-controlled study 5,170 patients within 24 hours after the onset of symptoms of a minor stroke or TIA to an initial loading dose of 300 mg clopidogrel followed by 75 mg/day for 90 days with aspirin at a dose of 75 mg/day for the for the 21 days, or to placebo plus aspirin 75 mg for 90 days. This study conducted in China found that the combination was superior to aspirin in reducing the risk of stroke in the first 90 days. The patients' selection did not include major stroke or patients who received thrombolytics.[82] Given that our patient received thrombolytic, aspirin is the preferred option.

Glycoprotein IIb/IIIa Inhibitors

Platelet glycoprotein IIb/IIIa inhibitors have also been studied in acute stroke. A placebo-controlled phase II trial of abciximab given within 24 hours of acute stroke showed a trend toward improved functionality in abciximab-treated patients, but the study was not powered to show the significance for this outcome.[83]

In another placebo-controlled, phase II study of patients with acute stroke, the direct thrombin inhibitor, argatroban, was associated with statistically significant improvements in neurologic symptoms and daily living activities.[84] The number of patients enrolled in this study was small, but the results show promise. Currently, the use of these agents is limited to clinical trials.

ENDOVASCULAR INTERVENTIONS

CASE 61-2, QUESTION 6: What other non-pharmacological interventions might be also considered for the acute treatment of stroke in P.C.?

A number of endovascular treatment options for ischemic stroke are available and include intra-arterial fibrinolytics, mechanical thrombectomy with coil retrievers such as the Mechanical Clot Retrieval System (Merci) or stent retrievers such as Solitaire FR and Trevo, combination intra-arterial thrombolytics with mechanical thrombectomy, mechanical clot aspiration with the Penumbra system, and acute angioplasty and stenting.[53]

Intra-arterial thrombolytics administration requires an experienced stroke center and careful selection to identify patients who would benefit. As with intravenous fibrinolytics, intra-arterial thrombolytics should be administered within 6 hours of onset of symptoms, in patients with occlusions of the middle cerebral artery who are not a candidates for intravenous alteplase. Urokinase is the only fibrinolytic with randomized trials that has been shown to be effective in clot lysis, resulting in recanalization and restoration of blood flow.[85],[86] While intra-arterial thrombolytics can be considered when intravenous fibrinolytics is predicted to fail (large vessel occlusion) or is contraindicated, these therapies, if available to be administered by a skillful interventional neuroradiologist, should be considered. Lack of identification of optimal dose and evidence of effectiveness in occlusions outside of the middle cerebral artery limit the widespread use of intra-arterial thrombolytics.[53] Mechanical removal of the clot has been evaluated alone or in combination with pharmacological fibrinolysis. Four devices are currently available: MERCI, Penumbra, Solitaire FR, and Trevo. The most current guidelines recommend using the stent retrievers (Solitaire or Trevo) over coil retrievers, such as Merci.

The most recent evidence with these devices is promising. In patients with stroke secondary to occlusions in the proximal anterior intracranial circulation, patients who underwent thrombectomy using a stent retriever device (Solitaire) after receiving intravenous alteplase reduced significantly the 90 days disability without increasing risk of ICH or mortality compared to intravenous alteplase monotherapy.[87] Similar results were also found in four other trials comparing endovascular therapy with intravenous thrombolytics to standard therapy with intravenous thrombolytics alone for documented large occlusions in the proximal anterior circulation. Intra-arterial thrombectomy reduced disability and improved outcomes.[88–91] These trials compared to earlier trials required angiographic confirmation by CT of an intracranial occlusion for eligibility, while earlier trials that did not require such confirmation or used older devices (Merci and Penumbra) did not find such benefit.[92–95]

Stroke Education

CASE 61-2, QUESTION 7: What information and instruction should be given to P.C. regarding future stroke symptoms?

Early treatment of acute stroke with available or investigational drugs appears to be the most important factor in determining optimal outcome. Nearly every clinical trial demonstrating some benefit of pharmacotherapy for acute stroke has shown the greatest effect for patients who are treated within a few hours of the onset of stroke symptoms. Immediate detection of stroke symptoms and initiation of treatment are imperative. The primary rate-limiting step in diagnosis and provision of medical care is recognition by the patient of stroke symptoms. Every patient who is at increased risk of stroke should be carefully instructed to seek emergent medical attention if they experience any weakness or paralysis, speech impairment, numbness, blurred vision or sudden loss of vision, or altered level of consciousness. These symptoms should be handled with the same urgency as the symptoms of a myocardial infarction. The pharmacist should ensure that P.C. and his caregivers know the symptoms of stroke and understand what to do if they occur.

Complications

CASE 61-2, QUESTION 8: What complications associated with stroke might P.C. experience?

Agitation, delirium, stupor, coma, cerebral edema, and increased intracranial pressure are other acute symptoms that can be associated with ischemic stroke. These symptoms correlate with the specific blood vessels that are affected, and the development of these complications in P.C. would depend on the progression of his stroke.

Seizures may occur in up to 20% of stroke patients. Pneumonia, pulmonary edema, cardiac arrest, deep vein thrombosis, and arrhythmias are commonly associated with ischemic stroke and should be managed as they occur. In P.C., these may occur soon after his stroke or be related to a rapidly developing neurologic event such as further infarction, hemorrhage, or severe cerebral edema. Pneumonia or deep venous thromboses are related primarily to inactivity, and the risk of these events will increase the longer P.C. remains immobile.

Stroke patients frequently experience psychologic reactions. The most common psychiatric complication is depression, occurring in 30% to 50% of patients.[96]

The severity of depression varies from mild to major depressive episodes. If the depression interferes with recovery and the rehabilitative process, it should be managed with the use of a selective serotonin reuptake inhibitor or other appropriate agent. Severe psychomotor depression may respond to CNS stimulants, such as methylphenidate or dextroamphetamine. Because of P.C.'s hypertension, stimulants should be used only with careful blood pressure monitoring.

Prognosis

CASE 61-2, QUESTION 9: After 4 days in the hospital, P.C.'s neurologic status is stabilized. Will further neurologic improvements be realized?

Neurologic deficits in stroke patients are not considered stable or fixed until at least 8 to 12 months have elapsed. During this time, neurologic function may return but rarely to normal. The prognosis after ischemic stroke depends on a variety of factors including age, hypertension, coma, cardiopulmonary complications, hypoxia, and neurogenic hyperventilation. However, infarction of the middle cerebral artery is associated with a poor chance for recovery. Recently, physical and occupational therapy techniques involving restriction of activity in the unaffected limb or limbs have proven to be effective in patients regaining lost function. Therefore, it is possible that P.C. will experience further neurologic improvement.

SECONDARY PREVENTION AFTER ISCHEMIC STROKE OR TIA

CASE 61-2, QUESTION 10: What antiplatelet or anticoagulation therapy would be recommended for secondary stroke prevention for P.C.?

Antiplatelet Therapy for Secondary Prevention

Because platelets play a key role in the formation of atheromatous clots, various antiplatelet drugs, such as aspirin, combination aspirin/dipyridamole, ticlopidine, clopidogrel, and cilostazol, have been studied for secondary prevention. Cilostazol is the only agent not approved by the Food and Drug Administration (FDA) for secondary prevention of ischemic strokes and TIAs arising from non-cardioembolic origin. These agents generally work by either preventing the formation of TXA_2 or increasing the concentration of prostacyclin. These actions seek to reestablish the proper balance between these two substances, thus preventing the adhesion and aggregation of platelets (Table 61-4). Around 22% relative risk reduction of stroke, myocardial infarction, or death is noted with these agents compared to placebo in patients with prior TIA or stroke.[97] Based on the current guidelines for non-cardioembolic ischemic stroke and TIAs secondary prevention, aspirin, clopidogrel, or combination aspirin/dypiridamole extended release are considered first-line therapy.[5]

ASPIRIN

The effectiveness of aspirin for secondary prevention of non-cardioembolic ischemic stroke and TIA is supported by evidence of high quality. At least 15 randomized trials, with 7 being placebo-controlled, have studied aspirin alone or in combination with other antiplatelet drugs in the prevention of vascular events.[45],[98–102]

Patients were enrolled in these studies for as long as 5 years after experiencing a vascular event (i.e., TIA, stroke, unstable angina, or myocardial infarction). Follow-up periods lasted from 1 to 6 years. The incidence of ischemic stroke or TIA ranged from 7% to 23%: the aspirin-treated patients experienced an average 22% decrease in relative risk of a stroke compared with those receiving placebo. In 10 trials that considered only TIA or stroke patients, there was a 24% relative risk reduction in the incidence of nonfatal stroke associated with the use of aspirin. The risk reduction rate is equal for men and women.[98],[103]

Dosages of aspirin used in clinical trials have ranged from 30 to 1,500 mg/day. In a meta-analysis of placebo-controlled studies comparing 900 to 1,500 mg/day of aspirin with similar studies of 300 to 325 mg/day, there was a 23% reduction in the risk of cerebrovascular events for patients receiving 900 to 1,500 mg/day and a 24% reduction in risk for patients receiving 300 to 325 mg/day.[97] A prospective comparison of aspirin doses in 3,131 patients showed a 14.7% frequency of nonfatal stroke or nonfatal myocardial infarction in patients receiving 30 mg of aspirin a day and a 15.2% frequency in patients receiving 283 mg of aspirin a day, a nonsignificant difference between these two doses.[104] The Swedish Aspirin Low-Dose Trial showed an 18% reduction in stroke in patients taking 75 mg of aspirin daily compared with placebo.[105] Helgason et al. compared the effects of 325, 650, 975, and 1,300 mg of aspirin a day in stroke patients.[106] Platelet aggregation studies were performed to determine the effects of aspirin. Eighty percent of patients had complete suppression of aggregation at a daily dose of 325 mg, an additional 5% responded at 650 mg/day, only 1% more responded at 975 mg/day, and there was no further response at 1,300 mg. As aspirin doses increase, so does the risk of gastrointestinal (GI) bleeding.[107]

The recommended dose for aspirin is 50 to 325 mg/day. The goal is to use the lowest effective aspirin dosage, thereby limiting the risk of GI adverse effects. In the

United States, a dose of 81 mg enteric-coated aspirin is usually started.

TICLOPIDINE

Ticlopidine is an antiplatelet agent approved only for the prevention of TIA and stroke for patients with a prior cerebral thrombotic event. By inhibiting ADP-induced platelet aggregation, its activity differs from that of aspirin. While effective in reducing risk of stroke, its use is limited by serious hematological and GI adverse effects.[108],[109]

CLOPIDOGREL

Clopidogrel is chemically related to ticlopidine and works by inhibiting platelet aggregation induced by ADP. A randomized, double-blind, international trial (Clopidogrel vs. Aspirin in Patients at Risk of Ischaemic Events [CAPRIE]) compared clopidogrel 75 mg/day with aspirin 325 mg/day.[110] Patients enrolled in the study had a history of atherosclerotic vascular disease manifested by recent ischemic stroke, myocardial infarction, or symptomatic peripheral vascular disease. Using intention-to-treat analysis, a 5.3% risk of an event in patients receiving clopidogrel and a 5.83% risk in patients receiving aspirin were observed. This represents a statistically significant relative risk reduction of 8.7%, favoring clopidogrel. On-treatment analysis showed a relative risk reduction of 9.4%, again in favor of clopidogrel. For patients whose primary condition for entry into CAPRIE was stroke, the relative risk reduction was 7.3%; however, this difference was not statistically significant. Patients receiving clopidogrel more frequently experienced rash and diarrhea compared with those receiving aspirin. Patients receiving aspirin were more frequently affected by upper GI distress, intracranial hemorrhage, and GI hemorrhage. Significant reductions in neutrophils occurred in 0.10% of patients on clopidogrel and in 0.17% of patients on aspirin. Some cases of thrombocytopenia purpura are reported in the literature.[111]

Clopidogrel is as effective and safe as aspirin. Clopidogrel is an alternative to aspirin in secondary prevention of stroke.[5] Polymorphisms in the hepatic enzymes involved in the metabolism and activation of clopidogrel (CYP 1A2, CYP3A4, CYP2C19) or within the platelet $P2Y_{12}$ receptor may affect clopidogrel's antiplatelet therapy. Similarly, drug interactions affecting the CYP2C19 P450 cytochrome can lead to decreased effectiveness of clopidogrel. Commonly prescribed proton pump inhibitors, such as omperazole, have been suggested to decrease efficacy of clopidogrel. It is suggested to avoid the combination of omeprazole and clopidogrel until more solid evidence is available.[5]

ASPIRIN/DIPYRIDAMOLE

Dipyridamole inhibits phosphodiesterase and augments prostacyclin-related platelet aggregation inhibition. Four large randomized clinical trials have evaluated the secondary prevention effect of aspirin and dipyridamole combination among patients with stroke or TIAs. Two European studies have shown benefit with a combination of aspirin and dipyridamole. In the first study, a combination of aspirin 325 mg/day and immediate release 75 mg dipyridamole three times/day was compared with placebo.[112] Results from this study showed that the combination reduced the combined risk of stroke and death by 33% and the risk of stroke by 38%. The Second European Stroke Prevention Study enrolled patients who had experienced a previous stroke or TIA and found that aspirin combined with dipyridamole was more effective than placebo, dipyridamole alone, and aspirin alone.[113]

A sustained-release formulation of dipyridamole was used for this study. A 37% relative risk reduction was found for the combination treatment, and a 23% relative risk reduction was found for aspirin alone. The dipyridamole dose for this study was 200 mg twice a day (BID), and the aspirin dose was 25 mg BID. Absolute risk reduction was approximately 1.5% annually. Headache occurred more frequently in patients receiving dipyridamole alone or in combination with aspirin. Bleeding complications were less frequent in patients receiving dipyridamole compared with aspirin alone. As a result of these findings, a combination product of aspirin and dipyridamole is available. The combination of sustained-release dipyridamole and aspirin is an acceptable alternative for secondary prevention of stroke when initial secondary prevention has failed.

In the 2006 open label European/Australian Stroke Prevention in Reversible Ischemia Trial (ESPRIT), with a mean follow-up of 3.5 years, the combination aspirin/dipyridamole was associated with an absolute risk reduction of 1%/year for the composite primary outcome of vascular mortality, nonfatal stroke, nonfatal MI, or major bleeding (13% vs. 16%) Bleeding rates were similar between the two groups. Combination aspirin/dipyridamole was discontinued secondary to headaches in 8.8% of patients. Of note, the aspirin dose ranged from 30 to 325 mg, and 83% of the patients took the extended release formulation of dipyridamole.[114]

Clopidogrel was compared with the combination aspirin and extended release dipyridamole in the non-inferiority Prevention Regimen for Effectively Avoiding Second Strokes trial.[115] Among the patients with non-cardioembolic ischemic stroke who were followed for a mean of 2.5 years, there was no difference in stroke rates between the two intervention arms. The risk of gastrointestinal hemorrhage was higher in the aspirin plus extended dipyridamole group compared to clopidogrel (4.1% vs. 3.6%). Clopidogrel was better tolerated with less bleeding and less headaches than the combination.

CILOSTAZOL

Cilostazol is a vasodilator and antiplatelet agent. It has action on intracellular cyclic AMP and is a phosphodiesterase-3 inhibitor that is used mainly for intermittent claudication in patients with peripheral artery disease.[116] In Asian studies, cilostazol 100 mg twice daily was found to equally reduce risk of vascular events compared to aspirin in non-cardioembolic stroke. However, headache, diarrhea, palpitations, dizziness, and tachycardia were more frequent with cilostazol than aspirin, leading to more discontinuation in therapy (20% vs. 12%).[117],[118] Given the ventricular tachycardia risk associated with cilostazol, it is contraindicated in patients with heart failure.[116]

WARFARIN AND ORAL ANTICOAGULANTS

Large randomized trials have compared oral anticoagulants with aspirin in the secondary prevention of stroke and TIA. In one study, aspirin 30 mg/day was compared with oral anticoagulants in doses adjusted to maintain an INR between 3.0 and 4.5.[119] This study was terminated early when the mortality rate attributable to major bleeding events in the anticoagulant group was double the rate in the aspirin group. In this study, there was no difference between anticoagulants and aspirin in the frequency of stroke. A second study compared warfarin, dosed to maintain the INR between 1.4 and 2.8, and aspirin 325 mg/day.[120]

Results from this study did not demonstrate a significant difference between aspirin and warfarin with regard to the prevention of stroke or major hemorrhagic events. However, minor hemorrhages were significantly more frequent among patients receiving warfarin. A third study was terminated early because of safety concerns in the warfarin arm of the study.[121] The target INR for this study was 2 to 3 in the warfarin arm compared with aspirin. The study was stopped owing to significantly higher rates of adverse events in individuals receiving warfarin and no difference in the risk of stroke. Events including major hemorrhage, myocardial infarction, or sudden death, and overall death were increased in those receiving warfarin. Warfarin is not generally recommended for secondary prevention of non-cardioembolic stroke. In secondary prevention of cardioembolic stroke originating from atrial fibrillation, warfarin or the newer oral anticoagulants are preferred first-line therapy.[47]

ASPIRIN COMBINED WITH CLOPIDOGREL

A major study has compared clopidogrel 75 mg/day with the combination of clopidogrel 75 mg/day and aspirin 75 mg/day.[122] There was no difference in the risk of recurrent stroke or other cardiovascular outcomes between the groups, but the combination therapy group had a significant increase in life-threatening bleeding. Some individuals may be resistant to aspirin's effects on platelets.[123] Although poorly understood and studied, aspirin resistance may be related to the presence of extra platelet sources of TXA_2 and an interaction with over-the-counter nonsteroidal anti-inflammatory drugs or high levels of circulating 11-dehydro-thromboxane B_2. Cyclooxygenase-2 expression is induced during human megakaryopoiesis and characterizes newly formed platelets.[124–126] There are no data to suggest that increasing the aspirin dose will overcome possible resistance to the antiplatelet effects of aspirin, but it is clear that an increased dose of aspirin increases the risk of major bleeding.

Surgical Interventions for Secondary Prevention

Carotid endarterectomy and carotid artery stenting are available to prevent ischemic stroke or TIAs. These are designed to either remove the source for an embolism or improve circulation to ischemic areas of the brain.

CAROTID ENDARTERECTOMY

Carotid endarterectomy (CEA) is a common surgical procedure for correcting atheromatous lesions responsible for causing a TIA or ischemic stroke. In this procedure, the carotid artery is surgically exposed, and the atheromatous plaque is excised. CEA combined with pharmacotherapy is considered first-line option for patients with a high-grade (>70% angiographic stenosis) atherosclerotic carotid stenosis.[5] Other patients do not benefit as much from such procedure, and the benefit does not outweigh the risk of such procedure. CEA is most effective for patients with an ulcerated lesion or stenotic clot that occludes greater than 70% of blood flow in the ipsilateral carotid artery and who experience symptoms of a TIA or stroke. Use of CEA in these patients may result in a 60% reduction in stroke risk during the subsequent 2 years.[127] Of six to eight patients treated with CEA, one stroke will be prevented within 2 years.[128] The use of CEA in other patient groups must be balanced with the risk of the procedure and life expectancy.[129] CEA is beneficial in patients with 50% to 69% stenosis of the carotid artery.[5] Surgery should be done within 2 weeks of a TIA or stroke. Generally, CEA is not indicated in patients who have permanent neurologic deficits or total occlusion of the carotid artery. CEA should be done by a surgeon with less than 6% morbidity and mortality rates.

Aspirin also has been used for prevention of restenosis after CEA. During the first year after CEA, 25% of patients will redevelop a stenotic lesion, with more than half of these causing a greater than 50% reduction in carotid blood flow.[103]

Stent placement is useful in preventing restenosis. Initial studies indicated that combination therapy with aspirin 325 mg/day and dipyridamole 75 mg three times a day would decrease the rate of restenosis. However, a subsequent randomized, placebo-controlled study using this regimen in post-CEA patients did not substantiate the earlier findings.[130] A combination of clopidogrel with aspirin has been shown to reduce postoperative ischemic events.[131]

Carotid Artery Angioplasty and Stenting

As an alternative to CEA, balloon angioplasty and placement of stents can also improve blood flow through a stenosed artery. This is a less invasive procedure associated with less patient discomfort and a shorter recovery time. During this procedure, a catheter with a small, deflated balloon is placed in the stenosed artery, and the atherosclerotic lesion is pressed into the arterial wall when the balloon is inflated. A small, plastic tube stent is placed in the artery to prevent the vessel from collapsing at the site of the lesion.

Carotid artery angioplasty and stenting (CAS) is another alternative. The initial study of this procedure was halted because of poor outcomes.[132] Subsequently, two studies have shown that CAS is not inferior to CEA, but further study is underway to determine whether CAS is more beneficial than CEA.[133],[134] CAS can be used in patients who are not candidates for CEA.

SPONTANEOUS INTRACEREBRAL HEMORRHAGE

Clinical Presentation and Treatment

CASE 61-3

QUESTION 1: S.P. is a 58-year-old man who is sitting at home watching television with his wife when he develops confusion, nausea, severe headache, and right arm weakness. His wife immediately calls for an ambulance and by the time paramedics arrive, S.P. is slumped in his chair and unresponsive. Significant past medical history includes poorly controlled hypertension, atrial fibrillation, and osteoarthritis. He takes lisinopril 10 mg by mouth daily, warfarin 4 mg by mouth daily, and acetaminophen 1,000 mg by mouth three times daily for these conditions. Upon presentation to the ED, his blood pressure is 184/114 mm Hg. A CT scan shows an intracerebral hemorrhage. Key electrolyte concentrations, coagulation studies, and blood counts are within normal limits except for an INR of 4.8 and a blood glucose level of 194 mg/dL.

S.P.'s neurologic symptoms and the appearance of blood on his CT scan are consistent with a diagnosis of intracerebral hemorrhage (ICH).

What risk factors for spontaneous intracerebral hemorrhage does S.P. have?

S.P.'s uncontrolled hypertension and his use of warfarin has increased his risk of ICH.[135] Specifically, use of warfarin increases the risk of ICH by two to five times depending on the degree of anticoagulation.[136],[137] Patients, such as S.P., who are taking warfarin before ICH and present with an INR >3 are at greater risk for developing larger hematomas, which are associated with worse outcomes, compared to those taking warfarin and presenting with a lower INR.[138],[139] Patients taking oral anticoagulants are also at greater risk of death after ICH versus those not taking anticoagulants.[136] Other drugs that may increase the risk of ICH include target-specific oral anticoagulants, such as dabigatran, rivaroxaban, apixaban, and edoxaban; heparin, LMWHs, fondaparinux, and other parenteral anticoagulants; aspirin and other antiplatelet agents; selective serotonin reuptake inhibitors; and sympathomimetics, such as amphetamines, phenylpropanolamine, cocaine, and caffeine-containing medications.[140–144] Additional risk factors for non-traumatic ICH include advanced age, history of stroke, diabetes, smoking, excessive alcohol consumption, African American ethnicity, and low cholesterol levels, especially in the absence of HMG-CoA reductase inhibitor use.[145],[146] Genetic predisposition does not play a role in most hemorrhagic strokes except for those caused by AVMs.

CASE 61-3, QUESTION 2: What are the key principles of therapy in patients presenting with spontaneous intracerebral hemorrhage?

Initial management of spontaneous ICH involves (1) preventing hematoma expansion and (2) preventing and managing elevated intracranial pressure.

To minimize hematoma expansion, anticoagulants should be reversed immediately in patients such as S.P., who present with drug-induced coagulopathies, and blood pressure should be carefully managed. Methods for preventing and managing elevated ICP include avoiding hypotonic fluids as well as medical and surgical methods. Ancillary therapies including treatment of fever and avoiding hypoglycemia and hyperglycemia are also suggested.

CASE 61-3, QUESTION 3: What pharmacotherapy should be initiated to reverse S.P.'s anticoagulant-induced coagulopathy?

Up to 20% of patients with ICH present with a drug-induced coagulopathy, like S.P.[147],[148] Because hematoma growth within the first 24 hours of ICH is directly associated with worse outcomes and reversal of warfarin-induced coagulopathies within 4 hours of ICH has been shown to limit hematoma expansion, it is important to reverse coagulopathies in a timely manner.[149],[150] All anticoagulant and antiplatelet medications should be immediately discontinued, and agents should be administered to remove the anticoagulant medication from the body and reverse its effect.[151] Although S.P. was using warfarin for prevention of ischemic stroke in the setting of atrial fibrillation, because of his acute ICH, the benefit of reversing the warfarin in order to improve neurologic outcome greatly outweighs the short-term risk of ischemic stroke resulting from anticoagulant reversal. If a patient has taken an oral anticoagulant within the last two hours, activated charcoal may be considered to prevent absorption; however, it is important to ensure the patient can tolerate enteral administration. Historically, fresh frozen plasma (FFP) has been used to reverse warfarin-induced coagulopathies in patients such as S.P.; however, prothrombin complex concentrates (PCCs) have recently become the recommended agents to rapidly reverse anticoagulation because of warfarin.[152] FFP contains all the clotting factors depleted by warfarin but can take several hours to thaw and administer and may be associated with pulmonary complications and edema because of the volume required. In contrast, PCCs may reverse the INR within minutes because they can be administered more rapidly. Additionally, PCCs are associated with a lower risk of volume overload and pose a lower risk of infection than FFP. Use of PCCs in this setting has been shown to more effectively limit hematoma expansion compared to FFP, but improvement in clinical outcomes has not been demonstrated to date.[153],[154] Three-factor PCCs contain factors II, IX, and X while 4-factor PCCs also includes factor VII. PCC availability may be limited by institutional policies, in part, because of the high cost of treatment relative to other therapeutic options.[155] Because the effect of PCC and FFP is short-lived, patients with warfarin-induced coagulopathy should concomitantly receive 10 mg of IV vitamin K (phytonadione) by slow infusion.[152]

Newer oral anticoagulants indicated for non-valvular atrial fibrillation include dabigatran, rivaroxaban, apixaban, and edoxaban.[156–158] Although data regarding management of ICH patients receiving these agents are limited, some experts suggest using a PCC product. Idarucizumab is a monoclonal antibody that can be used to reverse dabigatran. Agents for reversal of other target-specific anticagulants are under study. Importantly, dabigatran can be removed through hemodialysis. As with warfarin-induced coagulopathies, reversal agents should be administered promptly and activated charcoal should be considered.

Other drug-induced ICHs may occur in patients receiving heparin, LMWHs, the parenteral factor Xa inhibitor fondaparinux, and antiplatelet agents such as aspirin and clopidogrel. Protamine sulfate may be used for the reversal of heparin and LMWH, while fondaparinux activity may be antagonized with PCCs. No intervention has been shown to be clearly beneficial in patients experiencing ICH and taking antiplatelet agents, although studies are ongoing.[151]

To reverse his warfarin-induced coagulopathy, S.P. should receive a weight-based dose of a PCC product and 10 mg IV vitamin K by slow IV infusion.

CASE 61-3, QUESTION 4: How should S.P.'s acute hypertension be managed?

Excessive hypertension may expose patients with ICH to elevated risk of hematoma expansion, neurologic deterioration, and worse outcomes.[159],[160] Lower blood pressures have been suggested to potentially worsen prognosis; however, this phenomenon is not as well documented as it is with ischemic stroke.[161],[162] Several studies have shown that rapid blood pressure reduction to a SBP of less than 140 mm Hg is safe in patients with ICH presenting with hypertension.[163–166] Additionally, studies suggest that aggressive acute blood pressure control can improve functional outcomes and may be associated with a trend toward a reduction in death.[159],[163] It is important to note that patients presenting with SBPs above 220 mm Hg and those with very severe ICHs have not been well represented in studies.

Based on these studies, current guidelines suggest that lowering SBP to less than 140 mm Hg in patients presenting with an SBP 150 to 220 mm Hg and no contraindications to antihypertensive therapy is safe and may improve outcomes. In patients presenting with an SBP >220 mm Hg, it is recommended to initiate aggressive antihypertensive therapy with an IV infusion and to carefully monitor the patient.[151] Nicardipine and labetalol are most commonly used antihypertensive agents in patients with ICH, but hydralazine, nitroprusside, or nitroglycerin may be considered depending on the clinical situation. If labetalol is used to control acute blood pressure, it should be administered as IV boluses, potentially in combination with an IV infusion. Nicardipine is only administered as an IV infusion.

S.P.'s blood pressure exceeds 150 mm Hg, so IV antihypertensive therapy is indicated. It would be appropriate to initiate an IV nicardipine infusion at 5 mg/hour and titrate every 5 minutes to achieve an SBP of less than 140 mm Hg in S.P.

CASE 61-3, QUESTION 5: Hours after admission, S.P.'s mental status worsens, likely because of severely elevated ICPs. What therapy should S.P. receive for his elevated ICP?

Elevated ICP refers to excessive pressure inside the intracranial vault and may occur in patients with severe hemorrhagic and ischemic strokes as well as in those suffering from traumatic brain injury, brain tumors, hydrocephalus, and hepatic encephalopathy. It can lead to brain hypoxemia and cause herniation. S.P.'s worsened mental status may be consistent with elevated ICP. Other symptoms of elevated ICP include headache, vomiting, cranial

---

nerve palsies, and the combination of bradycardia, respiratory depression, and hypertension.

In patients with neurologic emergencies, such as S.P., hypotonic fluids such as dextrose 5% in water should be avoided in favor of isotonic fluids such as 0.9% sodium chloride (normal saline) and Lactated Ringers because hypotonic fluids can exacerbate cerebral edema and worsen ICP.[151] When considering fluids patients are receiving, it is important to evaluate both maintenance fluids patients are getting and the fluids in which IV medications are diluted. In patients with elevated ICPs, IV medications should be diluted in 0.9% sodium chloride rather than dextrose 5% in water or other hypotonic fluids whenever possible.

Treatment of elevated ICP involves patient care measures, pharmacotherapy, and surgical interventions. First, the head of the bed should be elevated to at least 30 degrees once it is clear that S.P. is not hypovolemic in order to minimize blood and fluid accumulation in the brain. Hyperventilation (increasing the patient's respiratory rate and/or the volume of air he breathes with each respiration) with a $PaCO_2$ goal of <30 mm Hg may be considered for a very short time in S.P. until other interventions can be implemented. Hyperventilation should not be continued long-term because it can compromise cerebral blood flow.

S.P. should receive aggressive analgesic medications, such as fentanyl and morphine. Sedatives, such as propofol, should also be administered.[151] Hyperosmolar agents, including intravenous mannitol, dosed at 0.25 to 1 g/kg every 4 to 6 hours, or hypertonic sodium chloride may be considered to establish an osmotic gradient that can facilitate the movement of fluid out of the brain, thus reducing ICP.[151],[167] Clinicians may place an intracranial pressure monitor or utilize neurologic exams to guide treatment with hyperosmolar agents. If an ICP monitor is used, hyperosmolar therapy would be indicated to maintain an ICP of <20 mm Hg while if an ICP monitor is not utilized, a worsening in neurologic exam consistent with elevated ICP would warrant therapy. If S.P. continues to exhibit elevated ICPs after hyperosmolar and aggressive analgesia and sedation, a continuous infusion of a neuromuscular blocking agent should be administered. Last-line measures that may be considered include use of a barbiturate coma.

In patients who develop hydrocephalus because of an ICH or another condition, a ventriculostomy may be employed. A ventriculostomy is a surgically placed drain that resides in the ventricle and is used to drain CSF. Finally, open craniotomy, or removal of a portion of the skull, in the area of edema, may be considered in highly selected situations; however, the efficacy of this approach is questionable in many patients.

CASE 61-3, QUESTION 6: What other ancillary therapies may be appropriate for S.P.?

S.P. may benefit from (1) maintenance of normothermia with acetaminophen if he develops a fever and (2) avoiding hypoglycemia or excessive hyperglycemia.

Although the clinical benefit of antipyretic therapy has not been clearly established in ICH, fever is associated with a worse prognosis.[168] It is recommended that S.P.'s body temperature should be monitored and acetaminophen may be administered to achieve normothermia.[151] Studies evaluating mild hypothermia are ongoing.

Both hypoglycemia and hyperglycemia should be avoided in hemorrhagic stroke. Hypoglycemia can directly lead to neurologic injury while hyperglycemia is associated with worsened neurologic outcome after from stroke. Current guidelines recommend avoiding both hypoglycemia and hyperglycemia but do not suggest a specific blood glucose range.[151] Considering that his blood glucose is markedly elevated, S.P. should be initiated on an insulin regimen in accordance with institutional policies.

Seizures can complicate approximately 16% of all strokes and may be difficult to observe because they are often non-convulsive.[151],[169] However, because studies of prophylactic antiepileptic therapy have failed to demonstrate consistent benefit and have sometimes indicated harm,[170] current guidelines do not recommend routine seizure prophylaxis.[151] Antiepileptic therapy should be initiated promptly if a patient develops seizures during or after the development of an ICH.

CASE 61-3, QUESTION 7: What secondary prevention strategies should be recommended for S.P. after he recovers from his ICH?

For S.P. and any patient who has suffered an ICH, key modifiable risk factors that should be addressed upon stabilization include maintaining blood pressure at less than 130/80 mm Hg, smoking cessation, treating sleep apnea, avoiding excessive alcohol use, and abstaining from cocaine and other illicit drugs.[151],[169]

REHABILITATION

CASE 61-4

QUESTION 1: Patient J.A. has had a stroke and has received appropriate acute care. He is ready to be discharged from the hospital but still has trouble walking, talking, and performing activities of daily living. For patients who require rehabilitative care after hospital treatment of an ischemic or hemorrhagic stroke, what interventions will aid their recovery?

Patients who have suffered ischemic and hemorrhagic strokes often require long-term rehabilitation after their acute treatment. Rehabilitation is directed at managing daily functions, enhancing existing neurologic function, and attempting to regain lost function. Considerations for daily functions include activities of daily living and bowel and bladder management through balanced pharmacologic interventions. Efforts should be made to allow patients to function independently with activities of daily living and manage the psychologic effects of stroke. Enhancement of current neurologic function and minimizing depression includes elimination of drugs that may compromise patients' memory and mental function. These include benzodiazepines, major tranquilizers, and sedating antiepileptic drugs.

Localized spasticity is a common complication after strokes. Spasticity affecting a single limb frequently responds to regional motor nerve blocks with botulinum toxin. Aggressive physical therapy is also essential to the management of spasticity. Systemic antispasticity agents such as diazepam, baclofen, or dantrolene sodium are not used routinely because of the risk for toxicity. They are used only when spasticity involves multiple parts of the body or is unresponsive to other therapies.

Other less common impediments to patients' recovery after stroke include decubitus ulcers, hypercalcemia, and heterotopic ossification (e.g., the laying down and calcification of a bone matrix in muscle surrounding major joints). Prevention through meticulous skin care is the key to the management of pressure ulcers. Mobilizing patients as soon as possible after stroke can prevent hypercalcemia and heterotopic ossification.

Principles of Infectious Diseases

B. Joseph Guglielmo

CORE PRINCIPLES	CHAPTER CASES
① Although acute infection generally is associated with an increased white blood cell count, fever, and localizing signs, these symptoms may be absent in less severe disease. More severe infection, including sepsis, may be associated with hypotension, disseminated intravascular coagulation, and end-organ dysfunction.	**Case 62-1 (Questions 1, 2) Figure 62-1**
② Other disease states, particularly autoimmune disease and malignancy, may mimic infectious diseases. Although it should be considered a diagnosis of exclusion, drug-induced fever should be ruled out, particularly in patients without other classic signs and symptoms of infection.	**Case 62-1 (Question 3)**
③ Site-specific signs and symptoms and host factors generally predict the most likely pathogens, and empirical antimicrobial therapy should be directed against these organisms. Rapid detection tests improve the efficiency identifying a pathogen; however, they are more costly than traditional methodology.	**Case 62-1 (Questions 4, 5, Tables 62-1, 62-2)**
④ Isolation of an organism may reflect infection; however, colonization and contamination must be ruled out to avoid unnecessary antimicrobial exposure. Once a pathogen is identified, susceptibility tests, particularly disk diffusion or broth dilution, can demonstrate the most active antimicrobial agents.	**Case 62-1 (Questions 6, 7, Tables 62-3 through 62-7)**
⑤ Once the site of infection is confirmed and the likely pathogens are identified, drug distribution to the site of infection, dosage, route of administration, antimicrobial toxicity, side effects, and costs, must be considered before selection of therapy.	**Case 62-1 (Questions 8–10, Table 62-8)**
⑥ Antimicrobial dosing should reflect site of infection, route of elimination, and pharmacokinetics and pharmacodynamics.	**Case 62-1 (Questions 11–13, Table 62-9)**
⑦ Antimicrobial failure may be related to pharmacologic factors (inadequate dosing, insufficient penetration to the site of infection, and inadequate duration) and host factors (presence of prosthetic material, undrained focus of infection, and immune status). Adjunct therapies, including pressors and volume repletion, may improve outcomes in critically ill patients.	**Case 62-1 (Questions 14–17)**

APPROACHING THE PROBLEM

The proper choice, dose, and duration of antimicrobial therapy are based on several factors. Before initiating therapy, it is important first to confirm an infectious versus noninfectious process. Once infection has been documented, the most likely site must be identified, and signs and symptoms (e.g., erythema associated with cellulitis) generally direct the clinician to the likely source. Because certain pathogens are known to be associated with a specific site of infection, empirical therapy often can be directed against these organisms. Additional laboratory tests, including the Gram stain, serologic analysis, and antimicrobial susceptibility testing, generally identify the primary pathogen and active agents. Spectrum of activity, established clinical efficacy, adverse effect profile, pharmacokinetic disposition, and cost considerations ultimately guide the choice of therapy. Once an agent has been selected, the dosage and duration should be based on the size of the patient, site of infection, route of elimination, and other factors.

ESTABLISHING THE PRESENCE OF AN INFECTION

CASE 62-1

QUESTION 1: R.G., a 63-year-old, 70-kg man in the intensive care unit, underwent emergency resection of his large bowel. He has been mechanically ventilated throughout his postoperative course. On day 20 of his hospital stay, R.G. suddenly becomes confused; his blood pressure (BP) drops to 70/30 mm Hg, with a heart rate of 130 beats/minute. His extremities are cold to the touch, and he presents with circumoral pallor. His temperature increases to 40°C (axillary), and his respiratory rate is 24 breaths/minute. Copious amounts of yellow–green secretions are suctioned from his endotracheal tube.

Physical examination reveals sinus tachycardia with no rubs or murmurs. Rhonchi with decreased breath sounds are observed on auscultation. The abdomen is distended, and R.G. complains of new abdominal pain. No bowel sounds can be heard, and the stool is guaiac positive. Urine output from the Foley catheter has been 10 mL/hour for the past 2 hours. Erythema is noted around the central venous catheter.

A chest radiograph demonstrates bilateral lower lobe infiltrates, and urinalysis reveals >50 white blood cells/high-power field (WBC/HPF), few casts, and a specific gravity of 1.015. Blood, endotracheal aspirate, and urine cultures are pending. Other laboratory values include the following:

Sodium (Na), 131 mEq/L (normal, 135–147)
Potassium (K), 4.1 mEq/L (normal, 3.5–5)
Chloride (Cl), 110 mEq/L (normal, 95–105)
CO_2, 16 mEq/L (normal, 20–29 mEq/L)

Blood urea nitrogen (BUN), 58 mg/dL (normal, 8–18)
Serum creatinine (SCr), 3.8 mg/dL (increased from 0.9 mg/dL at admission; normal, 0.6–1.2)
Glucose, 320 mg/dL (normal, 70–110)
Serum albumin, 2.1 g/dL (normal, 4–6)
Hemoglobin (Hgb), 10.3 g/dL (13.5–17.5 g/dL male patients)
Hematocrit (Hct), 33% (normal, 39%–49% [male patients])
WBC count, 15,600/μL (normal, 4,500–10,000/μL) with bands present
Platelets, 40,000/μL (normal, 130,000–400,000)
Prothrombin time (PT), 18 seconds (normal, 10–12)
Erythrocyte sedimentation rate (ESR), 65 mm/hour (normal, 0–20)
Procalcitonin, 1 mcg/L (normal <0.25mcg/L)
Which of R.G.'s signs and symptoms are consistent with infection?

R.G. has numerous signs and symptoms consistent with an infectious process. His WBC count (15,600/μL) is increased, and a "shift to the left" (presence of bands, i.e., immature neutrophils) is observed on the differential. An increased WBC count is commonly observed with infection, particularly with bacterial pathogens. The WBC differential in patients with a bacterial infection often demonstrates a shift to the left owing to the bone marrow response to infection. Although infection is usually associated with an increased WBC, overwhelming sepsis can also be associated with a markedly decreased WBC count. In less acute infection (e.g., uncomplicated urinary tract infection, localized abscess), the WBC count may remain within the normal range because less bone marrow response would be anticipated.

R.G.'s temperature is 40°C by axillary measurement. Fever is a common manifestation of infection, with oral temperatures generally greater than 38°C. Oral and axillary temperatures tend to be approximately 0.4°C lower compared with rectal measurement. As a result, R.G.'s temperature would be expected to be 40.4°C if his temperature had been taken rectally. In general, rectal measurement of temperature is a more reliable determination of fever. Some patients with overwhelming infection, however, may present with hypothermia with temperatures less than 36°C. Furthermore, patients with localized infections (e.g., uncomplicated urinary tract infection, chronic abscesses) may be afebrile.

The bilateral lower lobe infiltrates on R.G.'s chest radiograph, the presence of copious amounts of yellow–green secretions from his endotracheal tube, and the erythema surrounding his central venous catheter is also compatible with one or more infectious processes. Furthermore, R.G. has signs and symptoms consistent with sepsis.

ESTABLISHING THE SEVERITY OF AN INFECTION

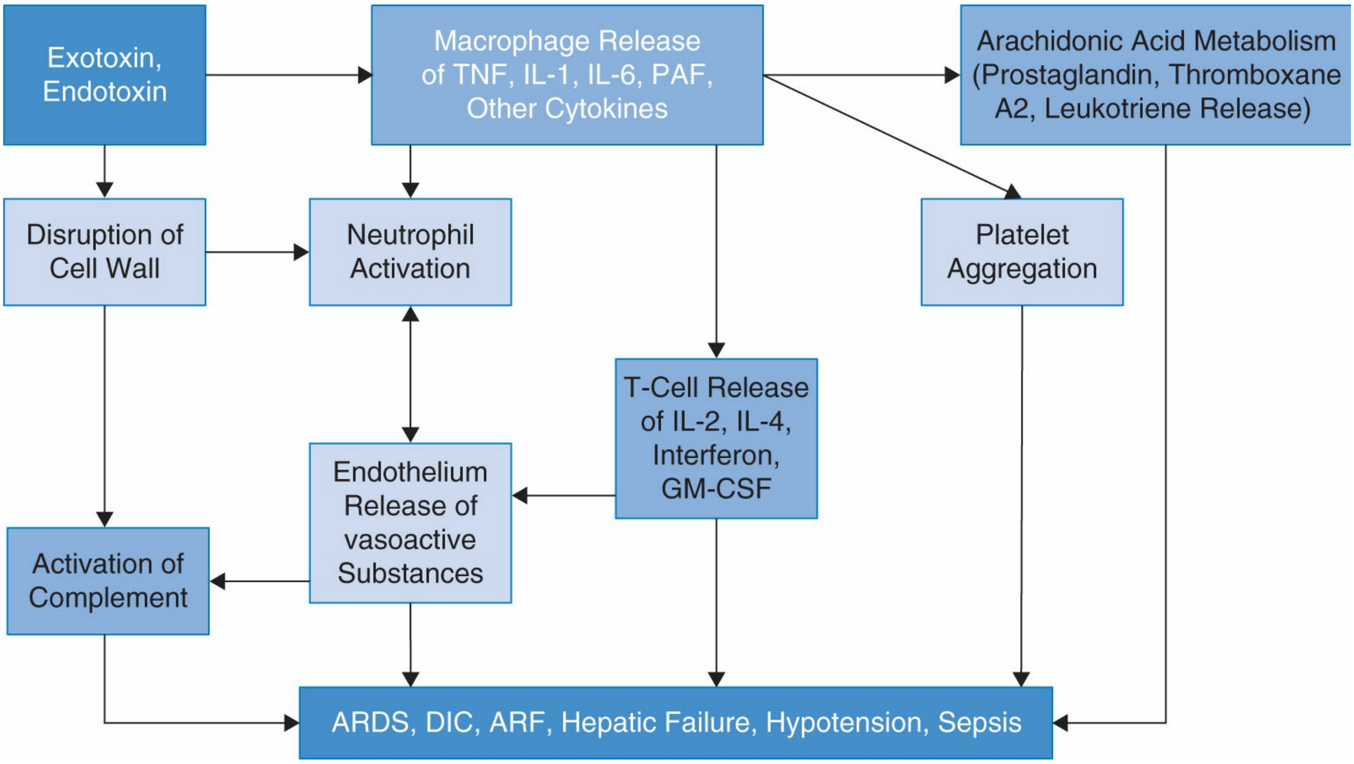
CASE 62-1, QUESTION 2: What signs and symptoms manifested by R.G. are consistent with a serious systemic infection?

The term sepsis, while a poorly defined syndrome, generally suggests a more systemic infection with the presence of pathogenic microorganisms and/or their toxins in the blood. A uniform system for defining the spectrum of disorders associated with sepsis has been established, but it remains difficult to precisely define.[1]

The pathogenesis of sepsis is complex (Fig. 62-1) and only partially understood.[2],[3] Gram-negative aerobes produce endotoxin that results in a cascade of endogenous mediator release, including tumor necrosis factor (TNF), interleukin 1 (IL-1) and interleukin 6 (IL-6), platelet-activating factor (PAF), and various other substances from mononuclear phagocytes and other cells. Although this initial stimulus commonly is associated with gram-negative endotoxin, other substances, including gram-positive exotoxin and fungal cell wall constituents, may also be associated with cytokine release. After release of TNF, IL-1, and PAF, arachidonic acid is metabolized to form leukotrienes, thromboxane A_2, and prostaglandins, particularly prostaglandin E_2 and prostaglandin I_2. IL-1 and IL-6 activate the T cells to produce interferon, IL-2, IL-4, and granulocyte-macrophage colony-stimulating factor (GM-CSF). Increased endothelial permeability ensues. Subsequently, the endothelium releases two hemodynamically active substances: endothelium-derived relaxing factor (EDRF) and endothelin-l. Activation of the complement cascade (fragments C3a and C5a) follows, with additional vascular abnormalities and neutrophil activation. Other potentially important agents in this cascade include adhesion molecules, kinins, thrombin, myocardial depressant substance, endorphins, and heat shock protein. The net result of this cascade involves several hemodynamic, renal, acid–base, and other disorders. Uncontrolled inflammation and coagulation have a particularly important role in this sepsis cascade.[3]

Hemodynamic Changes

Critically ill patients often have central intravenous (IV) lines in place for measuring cardiac output and systemic vascular resistance (SVR). In other words, these lines are placed in the pulmonary artery and allow for more precise measurement of critical hemodynamics. A normal SVR of 800 to 1,200 $\text{dyne}\cdot\text{s}\cdot\text{cm}^{-5}$ may fall to 500 to 600 $\text{dyne}\cdot\text{s}\cdot\text{cm}^{-5}$ in septic shock as a result of extensive vasodilation. In response to vasodilation the heart rate increases leading to increased cardiac output from a normal 4 to 6 L/minute to up to 11 to 12 L/minute in septic patients; stroke volume remains unchanged or decreased. In addition to reflex tachycardia causing a rise in heart rate, stress-induced catecholamine release (norepinephrine, epinephrine) also contributes. The initial increase in cardiac output generally is insufficient to overcome the vasodilatory state, and hypotension ensues. In overwhelming septic shock, myocardial depression may result, resulting in a decreased cardiac output. The combination of decreased cardiac output and decreased SVR results in hypotension often unresponsive to pressors and IV fluids. R.G. has hemodynamic evidence of septic shock. He is hypotensive (BP, 70/30 mm Hg) and tachycardic (130 beats/minute), presumably in response to vasodilation and catecholamine release.



Exotoxin, Endotoxin
Macrophage Release of TNF, IL-1, IL-6, PAF, Other Cytokines
Arachidonic Acid Metabolism (Prostaglandin, Thromboxane A2, Leukotriene Release)
Disruption of Cell Wall
Neutrophil Activation
Platelet Aggregation
T-Cell Release of IL-2, IL-4, Interferon, GM-CSF
Endothelium Release of vasoactive Substances
Activation of Complement
ARDS, DIC, ARF, Hepatic Failure, Hypotension, Sepsis

Figure 62-1 The sepsis cascade. ARDS, acute respiratory distress syndrome; ARF, acute renal failure; DIC, disseminated intravascular coagulation; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL-1, interleukin-1; IL-2, interleukin-2; IL-6, interleukin-6; PAF, platelet-activating factor; TNF, tumor necrosis factor.

Although vasodilation commonly occurs in sepsis, this dilation is unequal and chaotic. Some vascular beds constrict and others dilate, resulting in maldistribution of blood flow. In sepsis, blood generally is shunted away from the kidneys, mesentery, and extremities.

When sepsis has progressed to septic shock, blood flow to most major organs is decreased. Normal urine output of approximately 0.5 to 1.0 mL/kg/hour (30–70 mL/hour for a 70-kg patient) can decrease to less than 20 mL/hour in sepsis. The urine output for R.G. has decreased to 10 mL/hour, consistent with sepsis-induced perfusion abnormalities. Decreased blood flow to the kidney as well as mediator-induced microvascular failure can cause acute-tubular necrosis. R.G.'s uremia (BUN, 58 mg/dL) and increased serum creatinine concentration (3.8 mg/dL) are consistent with decreased renal perfusion secondary to sepsis. Decreased blood flow to the liver may result in "shock liver," in which liver function tests, including alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase, become elevated. The liver function tests for R.G. are not available; however, his serum albumin concentration is low (2.1 g/dL) and his PT of 18 seconds is prolonged. Decreased blood flow to the musculature classically is characterized by cool extremities, and decreased blood flow to the brain can result in decreased mentation. R.G. is confused, his extremities are cold, and the area around his mouth appears pale. All these signs and symptoms provide strong evidence that he is in septic shock.

Cellular Changes

The sepsis syndrome is associated with significant abnormalities in cellular metabolism. Glucose intolerance commonly is observed in sepsis, and patients with previously normal blood glucose levels may experience sudden increases in blood sugar. In some cases, a rise in glucose is one of the first signs of an infectious process. R.G.'s increased blood glucose concentration (320 mg/dL) is, therefore, consistent with infection. Other sensitive indicators of sepsis-associated inflammation include the ESR, C-reactive protein, and procalcitonin, nonspecific tests that are commonly elevated in various inflammatory states, including infection. The ESR, C-reactive protein, or procalcitonin can be used to follow the progression of infection; currently, R.G.'s ESR is elevated at 65 mm/hour. With appropriate management of infection, the ESR would be expected to decrease; inadequate treatment would be associated with persistent elevation of the ESR and C-reactive protein. Procalcitonin is a more specific indicator for infection than ESR or C-reactive protein and has been used as a tool to discontinue antibiotics in patients with noninfectious inflammation.[4] At present, R.G.'s procalcitonin is 1.0 mcg/L, which is consistent with infection-associated inflammation.

Respiratory Changes

Production of organic acids, such as lactate, increased glycolysis, decreased fractional extraction of oxygen, and abnormal delivery-dependent oxygen consumption are observed in sepsis.[3] This process leads to metabolic acidosis, with accompanying decreased serum bicarbonate levels. The lungs normally respond to metabolic acidosis in a compensatory manner with an increased respiratory rate (tachypnea), resulting in an increased elimination of arterial carbon dioxide. R.G.'s acid–base status is consistent with sepsis- associated metabolic acidosis (CO_2, 16 mEq/L) and compensatory respiratory alkalosis (respiratory rate, 24 breaths/minute).

A late complication of the above-mentioned sepsis cascade is acute respiratory distress syndrome (ARDS). ARDS initially was described as noncardiogenic pulmonary edema with severe hypoxemia caused by right-to-left intrapulmonary shunting resulting from atelectasis and edema-filled alveoli. The primary pathophysiology of ARDS is a breakdown in the natural integrity of the alveolar capillary network in the lung.[5] In the early phase of ARDS, patients have severe alveolar edema with large numbers of inflammatory cells, primarily neutrophils. The chronic phase of ARDS (10–14 days after development of the syndrome) is associated with significant lung destruction. Emphysema, pulmonary vascular obliteration, and fibrosis commonly are observed. Severe ARDS is associated with ratios of arterial oxygen level to fraction of inspired oxygen ($\text{Pao}_2/\text{FIO}_2$) of less than 100, low

lung compliance, a need for high positive end-expiratory pressure (PEEP), and other respiratory maneuvers. At present, the treatment for this syndrome primarily is supportive, including mechanical ventilation, high inspired oxygen, and PEEP. If patients fail to show improved gas exchange by day 7, the mortality associated with ARDS is high (>80%).[6] Although R.G. currently does not have ARDS, the severity of his sepsis strongly suggests he may develop this complication.

Hematologic Changes

Disseminated intravascular coagulation (DIC) is a well-recognized sequel of sepsis. Huge quantities of clotting factors and platelets are consumed in DIC as widespread coagulation and inflammation take place throughout the circulatory system.[3] As a result, the ratio of prothrombin time (PT) to international normalized ratio (INR) and the activated partial thromboplastin time (aPTT) are prolonged, and the platelet count commonly is decreased in sepsis. Decreased fibrinogen levels and increased fibrin split products generally are diagnostic for DIC. The PT of 18 seconds and the decreased platelet count of 40,000/μL in R.G. are consistent with sepsis-induced DIC.[3]

Neurologic Changes

Central nervous system (CNS) changes, including lethargy, disorientation, confusion, and psychosis, are commonly observed in septic patients. Altered mental status is a well-recognized symptom associated with CNS infections, such as meningitis and brain abscess. These changes, however, are also commonly observed with other sites of infection. R.G.'s confused state is consistent with that expected with septic shock.[2–3]

PROBLEMS IN THE DIAGNOSIS OF AN

INFECTION

CASE 62-1, QUESTION 3: R.G.'s medical history includes temporal arteritis and seizures chronically treated with corticosteroids and phenytoin. Perioperative "stress doses" of hydrocortisone recently were administered because of his surgical procedure. What medications or disease states confuse the diagnosis of infection?

Confabulating Variables

Various factors, including major surgery, acute myocardial infarction, and initiation of corticosteroid therapy, are associated with an increased WBC count. Unlike infection, however, a shift to the left does not occur with these disease states or drugs. In R.G., the stress dose of hydrocortisone and his recent surgical procedure might have contributed to the increased WBC count. The presence of bands in this patient, however, strongly suggests a bone marrow response to an infectious process.

Drug Effects

The ability of corticosteroids to mimic or mask infection is noteworthy. Corticosteroids are associated with an increased WBC count and glucose intolerance with the initiation of therapy or when doses are increased. Furthermore, some patients experience corticosteroid-induced mental status changes that may mimic those associated with sepsis. Although corticosteroids mimic infection, they also have the ability to mask infection. For example, bowel perforation in a patient with ulcerative colitis would result in significant peritoneal contamination. Considering their potent anti-inflammatory effects, concomitant receipt of glucocorticoids may, however, reduce the classic findings of peritonitis. Furthermore, corticosteroids can reduce and sometimes ablate the febrile response. Thus, these corticosteroid-treated patients may be asymptomatic but at great risk for gram-negative septic shock.

Another example of the influence of corticosteroids on the diagnosis of infection relates to neurosurgical procedures. Certain neurosurgical procedures are associated with significant trauma to the meninges; however, the patient often is asymptomatic while receiving high-dose dexamethasone, a corticosteroid commonly used to reduce the inflammation and swelling associated with neurosurgical procedures. When the dexamethasone dose is decreased, the patient subsequently may experience classic meningismus, including stiff neck, photophobia, and headache. The lumbar puncture may demonstrate cloudy cerebrospinal fluid (CSF), an elevated WBC count, high CSF protein, and low CSF glucose. Although the signs and symptoms are consistent with infectious bacterial meningitis, if no bacteria grow from the CSF sample, this disease state represents an aseptic meningitis (i.e., inflammation of the meninges without an infectious origin).[7] Certain drugs may cause aseptic meningitis, including nonsteroidal anti-inflammatory agents, sulfonamides, and certain antiepileptics.[8]

Fever

Fever is also a common finding with autoimmune diseases, such as systemic lupus erythematosus and temporal arteritis, or with sarcoidosis, chronic liver disease, and familial Mediterranean fever.[9],[10] Acute myocardial infarction, pulmonary embolism, postoperative pulmonary atelectasis, and certain cancers are also commonly associated with fever. Factitious fever or self-induced disease must be considered in certain patients. More recent evaluations of fever of unknown origin have resulted in an inability to diagnose the etiology of the fever; in many instances, the fever has resulted in the unnecessary use of antibiotics.[10] After infection, autoimmune disease, and malignancy have been ruled out, drug fever should be considered. Drugs, including certain antimicrobials and antiepileptics, have been associated with drug fever. Drug fever generally occurs after 7 to 10 days of therapy and resolves within 48 hours of the drug's discontinuation.[11] Some clinicians claim that patients with drug fever generally feel "well" and are unaware of their fever. A rechallenge with the offending agent usually results in recurrence of fever within hours of administration. Drug fever should be considered a diagnosis of exclusion, however, and should be considered only after eliminating the presence of other disease states.

In summary, R.G. has an autoimmune disease, temporal arteritis, which is known to be associated with fever. Similarly, his corticosteroid administration and phenytoin use may confound the diagnosis of infection. His other signs and symptoms, however, strongly suggest that R.G.'s problems are of an infectious origin.

ESTABLISHING THE SITE OF THE INFECTION

CASE 62-1, QUESTION 4: What are the most likely sources of R.G.'s infection?

Independent of the presumed site of infection, in septic patients a series of blood samples for culture tests must be drawn to demonstrate the presence of bacteremia. After blood culture sampling, a thorough physical examination often documents the source of infection. Urosepsis, the most common cause of nosocomial infection, may be associated with dysuria, flank pain, and abnormal urinalysis.[12] Tachypnea, increased sputum production, altered chest radiograph, and hypoxemia may direct the clinician toward a pulmonary source. Evidence for an infected IV line

---

might include pain, erythema, and purulent discharge around the IV catheter. Other potential sites of infection include the peritoneum, pelvis, bone, and CNS.

R.G. has several possible sites of infection. The copious production of yellow–

green sputum, tachypnea, and the altered chest radiograph suggest the presence of pneumonia. The abdominal pain, absent bowel sounds, and recent surgical procedure, however, suggest an intra-abdominal source.[13] Further, the abnormal urinalysis (>50 WBC/HPF) and the erythema around the central venous catheter suggest urinary tract and intravenous catheter infections, respectively.

DETERMINING LIKELY PATHOGENS

CASE 62-1, QUESTION 5: What are the most likely pathogens associated with R.G.'s infection(s)?

R.G. has several possible sources of infection and likely pathogens. Table 62-1 provides a classification of infectious organisms (e.g., gram-positive, gram-negative, aerobic, and anaerobic), and Table 62-2 lists the most likely organisms associated with sites of infection. Bacterial pneumonia is caused by various pathogens, including Streptococcus pneumoniae, Enterobacteriaceae, and "atypical" pathogens (e.g., Legionella pneumophila).[14] However, empirical antimicrobial therapy directed against all the above organisms is not necessary in all patients. Community-acquired pneumonia in normal hosts is generally associated with bacterial, S. pneumoniae, Haemophilus influenzae, and "atypical" bacterial pathogens.[15] In contrast, nosocomial (acquired in hospital or in other health care facilities, e.g., nursing home) pneumonia is associated with gram-negative bacilli (e.g., Escherichia coli, Klebsiella species, Enterobacter species, and Pseudomonas aeruginosa) and Staphylococcus aureus. If the pneumonia is a result of a gastric aspiration, empirical antibacterial treatment of mouth anaerobes generally takes place; however, their true pathogenicity in aspiration pneumonia is not clear. For the empirical treatment of hospital-associated pneumonia or ventilator-associated pneumonia, knowledge of a hospital epidemiology is useful. If P. aeruginosa or Enterobacter cloacae predominate in an institution, then broad-spectrum agents should be used directed against these pathogens. Similarly, prior or concurrent receipt of antimicrobial therapy significantly impacts the choice of empirical therapy. Age is an important determinant in the epidemiology of infection. For example, meningitis in a neonate is commonly caused by group B streptococci, E. coli, and Listeria monocytogenes, whereas these bacteria are uncommon meningitis pathogens in normal adults. The presence of concomitant diseases, such as chronic obstructive pulmonary disease (COPD) or alcohol and IV drug use, also influences the specific pathogen. As an example, patients with COPD-associated pneumonia are more likely to be infected by S. pneumoniae and H. influenzae, whereas chronic alcoholics are more likely to have Klebsiella species as a source of pneumonia.

Table 62-1

Classification of Infectious Organisms

1. Bacteria
    - Aerobic
        - Gram-positive
            - Cocci
                - Streptococci: pneumococcus, viridans streptococci; group A streptococci
                - Enterococcus
                - Staphylococci: Staphylococcus aureus, Staphylococcus epidermidis
            - Rods (bacilli)
                - Corynebacterium
                - Listeria
        - Gram-negative
            - Cocci
                - Moraxella
                - Neisseria (Neisseria meningitidis, Neisseria gonorrhoeae)
        - Rods
            - Enterobacteriaceae (Escherichia coli, Klebsiella, Enterobacter, Citrobacter, Proteus, Serratia, Salmonella, Shigella, Morganella, Providencia)
            - Campylobacter
            - Pseudomonas
            - Helicobacter
            - Haemophilus (coccobacilli morphology)
            - Legionella
    - Anaerobic
        - Gram-positive
            - Cocci
                - Peptococcus
                - Peptostreptococcus
            - Rods (bacilli)
                - Clostridia (Clostridium perfringens, Clostridium tetani, Clostridium difficile)
                - Propionibacterium acnes
        - Gram-negative
            - Cocci
                - None
            - Rods (bacilli)
                - Bacteroides (Bacteroides fragilis, Bacteroides melaninogenicus)
                - Fusobacterium
                - Prevotella
2. Fungi
    - Aspergillus, Candida, Coccidioides, Cryptococcus, Histoplasma, Mucor, Tinea, Trichophyton
3. Viruses
    - Influenza; hepatitis A, B, C, D, E; human immunodeficiency virus; rubella; herpes; influenza; cytomegalovirus; respiratory syncytial virus; Epstein–Barr virus; severe acute respiratory syndrome (SARS) virus
4. Chlamydiae
    - Chlamydia trachomatis
    - Chlamydia psittaci
    - Chlamydophila pneumoniae
    - Lymphogranuloma venereum (LGV)
5. Rickettsiae
    - Rocky Mountain spotted fever, Q fever
    - Ureaplasma
6. Mycoplasmas

Mycoplasma pneumoniae, Mycoplasma hominis

7. Spirochetes
    Treponema pallidum, Borrelia burgdorferi (Lyme disease)
8. Mycobacteria
    Mycobacterium tuberculosis
    Mycobacterium avium intracellulare

Table 62-2

Site of Infection: Suspected Organisms

Site/Type of Infection	Suspected Organisms
1. Respiratory	
Pharyngitis	Viral, group A streptococci
Otitis	Viral, Haemophilus influenzae, Streptococcus pneumoniae, Moraxella catarrhalis
Acute sinusitis	Viral, S. pneumoniae, H. influenzae, M. catarrhalis
Chronic sinusitis	Anaerobes, Staphylococcus aureus (as well as suspected organisms associated with acute sinusitis)
Epiglottitis	Viral, H. influenzae
Pneumonia	
Community-Acquired	
Normal host	S. pneumoniae, viral, mycoplasma
Aspiration	Normal aerobic and anaerobic mouth flora
Pediatrics	S. pneumoniae, H. influenzae
COPD	S. pneumoniae, H. influenzae, Legionella, Chlamydia, Mycoplasma
Alcoholic	S. pneumoniae, Klebsiella
Hospital-Acquired	
Aspiration	Mouth anaerobes, aerobic gram-negative rods, S. aureus
Neutropenic	Molds, aerobic gram-negative rods, S. aureus
HIV	Molds, Pneumocystis, Legionella, Nocardia, S. pneumoniae, Pseudomonas
2. Urinary Tract	
Community-acquired	Escherichia coli, other gram-negative rods, S. aureus, Staphylococcus epidermidis, enterococci
Hospital-acquired	Resistant aerobic gram-negative rods, enterococci
3. Skin and Soft Tissue	
Cellulitis	Group A streptococci, S. aureus
IV catheter infection	S. aureus, S. epidermidis
Surgical wound	S. aureus, gram-negative rods
Diabetic ulcer	S. aureus, gram-negative aerobic rods, anaerobes
Furuncle	S. aureus

1. Intra-abdominal	Bacteroides fragilis, E. coli, other aerobic gram-negative rods, enterococci
2. Gastroenteritis	Salmonella, Shigella, Helicobacter, Campylobacter, Clostridium difficile, amoeba, Giardia, viral, enterotoxigenic-hemorrhagic E. coli
4. Endocarditis	
Preexisting valvular disease	Viridans streptococci
IV drug user	S. aureus, aerobic gram-negative rods, enterococci, fungi
Prosthetic valve	S. epidermidis, S. aureus
5. Osteomyelitis and Septic Arthritis	S. aureus, aerobic gram-negative rods
6. Meningitis	
<2 months	E. coli, group B streptococci, Listeria
2 months–12 years	S. pneumoniae, Neisseria meningitidis, H. influenzae
Adults	S. pneumoniae, N. meningitidis
Hospital-acquired	S. pneumoniae, N. meningitidis, aerobic gram-negative rods
Postneurosurgery	S. aureus, aerobic gram-negative rods

COPD, chronic obstructive pulmonary disease; IV, intravenous.

Immune status is an important predictor of likely pathogens. HIV/AIDS patients or those receiving Atgam, cyclosporine (or tacrolimus), sirolimus, and corticosteroids have lymphocyte deficiency or dysfunction-associated infections, including those caused by cytomegalovirus, Pneumocystis jiroveci, atypical mycobacteria, and Cryptococcus neoformans. Patients with leukemia and neutropenia are at risk for infection caused by aerobic gram-negative bacilli, including P. aeruginosa, Candida species, and Aspergillus species, as well as the above-mentioned pathogens.

In R.G., the abdomen, respiratory tract, urinary tract, and IV catheter are all potential sites of infection. Intra-abdominal infection is likely caused by aerobic gram-negative enteric bacteria, Bacteroides fragilis, and possibly enterococcus; nosocomial urinary tract infection is usually caused by aerobic gram-negative bacteria. R.G.'s pneumonia could be attributable to gram-negative bacilli and staphylococci, as well as other organisms. Furthermore, his long-term use of corticosteroids may predispose him to infection caused by more opportunistic organisms, including Legionella, P. jiroveci, and fungi. Lastly, his IV catheter infection suggests infection caused by staphylococci, including Staphylococcus epidermidis and Staphylococcus aureus.

MICROBIOLOGIC TESTS AND SUSCEPTIBILITY

OF ORGANISMS

CASE 62-1, QUESTION 6: A Gram stain of R.G.'s tracheal aspirate shows gram-negative bacilli. What tests may assist with the identification of the pathogen(s)?

Once the site of infection has been determined and host defense and other epidemiologic factors have been evaluated, additional tests can be performed to identify the pathogen. The Gram stain uses crystal violet solution and iodine staining bacteria gram positive or gram negative; some organisms are gram variable. In addition, the shape of the organism (cocci, bacilli) is readily apparent with the use of the Gram stain. Streptococci and staphylococci are gram-positive cocci, whereas E. coli, E. cloacae, and P. aeruginosa appear as gram-negative bacilli (Table 62-1).[16] If the Gram stain of the tracheal aspirate demonstrates gram-positive cocci in clusters, empirical antistaphylococcal therapy is indicated. In contrast, if the Gram stain shows gram-negative rods, antimicrobials with activity against these pathogens should be used.

Similar to the Gram stain in bacterial infection, the India ink and potassium hydroxide stains are helpful in the identification of certain fungi. The acid-fast bacilli stain is critical in the diagnosis of infection caused by Mycobacterium tuberculosis or atypical mycobacteria.

In R.G.'s case, the Gram stain suggests that antimicrobials active against gram-negative bacilli should be used. Table 62-3 provides a classification of antibacterials (e.g., different generations of cephalosporins). Tables 62-4, 62-5, and 62-6 list in-vitro susceptibilities of aerobic gram-positive, gram-negative, and anaerobic bacteria, respectively.

Culture and Susceptibility Testing

Culture and susceptibility testing provides final identification of the pathogen, as well as information regarding the likely effectiveness of various antimicrobials. Although these tests provide more information than the Gram stain, they generally require 18 to 24 hours to complete. After the pathogen has been identified, Table 62-7 can be used in conjunction with institution-specific susceptibility studies to select the most appropriate antimicrobial.

Table 62-3

Classification of Antibacterials

β-Lactam Antibiotics

- Cephalosporins
  - First-generation
    - Cefadroxil (Duricef)
    - Cefazolin (Ancef)
    - Cephalexin (Keflex)
  - Second-generation
    - Cefaclor (Ceclor)
    - Cefamandole (Mandol)[a]
    - Cefonicid (Monocid)
    - Ceforanide (Precef)
    - Cefotetan (Cefotan)
    - Cefoxitin (Mefoxin)
    - Cefprozil (Cefzil)
    - Cefuroxime (Zinacef)
    - Cefuroxime axetil (Ceftin)
  - Third-generation
    - Cefdinir (Omnicef)
    - Cefditoren (Spectracef)
    - Cefixime (Suprax)
    - Cefotaxime (Claforan)
    - Cefpodoxime proxetil (Vantin)
    - Ceftazidime (Fortaz)
    - Ceftibuten (Cedax)
    - Ceftizoxime (Cefizox)
    - Ceftriaxone (Rocephin)
  - Fourth-generation
    - Cefepime (Maxipime)
  - Fifth-generation
    - Ceftaroline (Teflaro)
  - Penicillinase-resistant penicillins
    - Isoxazolyl penicillins (dicloxacillin, oxacillin, cloxacillin)
    - Nafcillin (Unipen)
  - Combination with β-lactamase inhibitors
    - Augmentin (amoxicillin plus clavulanic acid)
    - Avycaz (ceftazidime plus avibactam)
    - Timentin (ticarcillin plus clavulanic acid)[a]
    - Unasyn (ampicillin plus sulbactam)
    - Zerbaxa (ceftolozane plus tazobactam)
    - Zosyn (piperacillin plus tazobactam)
- Aminoglycosides
  - Amikacin (Amikin)
  - Gentamicin (Garamycin)
  - Neomycin (Mycifradin)
  - Netilmicin (Netromycin)
  - Streptomycin
  - Tobramycin (Nebcin)
- Protein synthesis inhibitors
  - Azithromycin (Zithromax)
  - Clarithromycin (Biaxin)
  - Clindamycin (Cleocin)
  - Chloramphenicol (Chloromycetin)

- Dalfopristin/Quinupristin (Synercid)
  - Dirithromycin (Dynabac)
  - Erythromycin (Erythrocin)
  - Fidaxomicin (Dificid)
  - Linezolid (Zyvox)
  - Tedizolid (Sivestro)
  - Telithromycin (Ketek)
  - Tetracyclines (doxycycline, minocycline, tetracycline, tigecycline)
- Carbacephems
  - Loracarbef (Lorabid)
- Monobactams
  - Aztreonam (Azactam)
- Penems
  - Doripenem (Doribax)
  - Ertapenem (Invanz)
  - Imipenem (Primaxin)
  - Meropenem (Merem)
- Penicillins
  - Natural penicillins
    - Penicillin G
    - Penicillin V
  - Aminopenicillins
    - Ampicillin (Omnipen)
    - Amoxicillin (Amoxil)
    - Bacampicillin (Spectrobid)[a]
- Folate inhibitors
  - Sulfadiazine
  - Sulfadoxine (Fansidar)
  - Trimethoprim (Trimpex)
  - Trimethoprim-sulfamethoxazole (Bactrim, Septra)
- Quinolones
  - Ciprofloxacin (Cipro)
  - Gemifloxacin (Factive)
  - Levofloxacin (Levoquin)
  - Moxifloxacin (Avelox)
  - Norfloxacin (Noroxin)
  - Ofloxacin (Floxin)
- Dalbavancin (Dalvance)
- Daptomycin (Cubicin)
- Oritavancin (Orbactiv)
- Telavancin (Vibativ)
- Vancomycin (Vancocin)
- Metronidazole (Flagyl)

[a] Not on the US market.

[a] Nonpneumococcal streptococci.

[b] Usually requires combination therapy (e.g., ampicillin or ampicillin and ceftriaxone) endocarditis.

[c] Levofloxacin (e.g., gemifloxacin, moxifloxacin) is more active than ciprofloxacin against staphylococci and streptococci.

[d] Active against Enterococcus faecium but unpredictable against E. faecalis.

[e] Cefotaxime, ceftizoxime, ceftriaxone, cefoperazone. Ceftazidime has comparatively inferior antistaphylococcal and antipneumococcal activity. Cefotaxime, ceftriaxone, and cefepime are the most reliable cephalosporins versus Streptococcus pneumoniae.

[f] Active versus vancomycin-resistant E. faecium.

MR, methicillin resistant; TGC, third-generation cephalosporin.

Table 62-7

Antimicrobials of Choice in the Treatment of Bacterial Infection

Organism	Drug of Choice	Alternatives	Comments
Aerobes			
Gram-positive cocci			
Streptococcus pyogenes (group A streptococci)	Penicillin	Clindamycin, macrolide, cephalosporin	Clindamycin is the most reliable alternative for penicillin-allergic patients.
Streptococcus pneumoniae	Ceftriaxone, ampicillin, oral	Macrolide, cephalosporin,	Although the incidence of penicillin-nonsusceptible pneumococci is

	amoxicillin	doxycycline	20%–30%, high-dose penicillin or amoxicillin is active against most of these isolates. Penicillin-resistant pneumococci commonly demonstrate resistance to other agents, including erythromycin, tetracyclines, and cephalosporins. Antipneumococcal quinolones (gemifloxacin, levofloxacin, moxifloxacin), ceftriaxone, and cefotaxime are options for treatment of high-level penicillin-resistant isolates.
Enterococcus faecalis	Ampicillin ± gentamicin	Piperacillin-tazobactam; vancomycin ± gentamicin; daptomycin, linezolid, tigecycline	Most commonly isolated enterococcus (80%–85%). Most reliable antienterococcal agents are ampicillin (penicillin, piperacillin-tazobactam), vancomycin, and linezolid. Monotherapy generally inhibits but does not kill the enterococcus. Daptomycin is unique in its bactericidal activity against enterococci. Aminoglycosides must be added to ampicillin or vancomycin to provide bactericidal activity. High-level aminoglycoside resistance should be determined for endocarditis.

Enterococcus faecium	Vancomycin ± gentamicin	Linezolid, daptomycin, dalfopristin/quinupristin (D/Q), oritavancin, tigecycline	Second most common enterococcal organism (10%–20%) and is more likely than E. faecalis to be resistant to multiple antimicrobials. Most reliable agents are daptomycin, D/Q, and linezolid. Monotherapy generally inhibits but does not kill the enterococcus. Aminoglycosides or ceftriaxone must be added to cell wall–active agents to provide bactericidal activity. Ampicillin and vancomycin resistance is common. Daptomycin, D/Q, and linezolid are drugs of choice for vancomycin-resistant isolates.
Staphylococcus aureus (methicillin-resistant)	Nafcillin, oxacillin	Cefazolin, vancomycin, clindamycin, dalbavancin, linezolid, oritavancin	10%–15% of isolates inhibited by penicillin. Most isolates susceptible to nafcillin, cephalosporins, trimethoprim-sulfamethoxazole, and clindamycin. First-generation cephalosporins are equal to nafcillin. Most second- and third-generation cephalosporins adequate in the treatment of infection (exceptions include ceftazidime and cefonicid). Methicillin-resistant S. aureus must be treated with vancomycin; however, trimethoprim-sulfamethoxazole, daptomycin, D/Q,
	Vancomycin	Trimethoprim-sulfamethoxazole, minocycline, daptomycin, tigecycline, telavancin, ceftaroline	

			linezolid, vancins, doxycycline, or minocycline can be used.
Staphylococcus epidermidis (methicillin-resistant)	Nafcillin, oxacillin	Cefazolin, vancomycin, clindamycin	Most isolates are β-lactam-, clindamycin-, and trimethoprim-sulfamethoxazole–resistant. Most reliable agents are vancomycin, daptomycin, D/Q, and linezolid. Rifampin is active and can be used in conjunction with other agents; however, monotherapy with rifampin is associated with development of resistance.
	Vancomycin	Daptomycin, linezolid, D/Q	
Gram-positive Bacilli			
Diphtheroids	Penicillin	Cephalosporin	
Corynebacterium jeikeium	Vancomycin	Erythromycin, quinolone	
Listeria monocytogenes	Ampicillin (±gentamicin)	Trimethoprim-sulfamethoxazole	
Gram-negative Cocci			
Moraxella catarrhalis	Trimethoprim-sulfamethoxazole	Amoxicillin-clavulanic acid, erythromycin, doxycycline, second- or third-generation cephalosporin	
Neisseria gonorrhoeae	Ceftriaxone		
Neisseria meningitidis	Penicillin	Third-generation cephalosporin	
Gram-negative Bacilli			
Campylobacter fetus	Imipenem	Gentamicin	
Campylobacter jejuni	Azithromycin	A tetracycline, amoxicillin-clavulanic acid, quinolone	
Enterobacter	Trimethoprim-sulfamethoxazole	Quinolone, carbapenem, aminoglycoside	Not predictably inhibited by third-generation cephalosporins. Carbapenems, quinolones, trimethoprim-sulfamethoxazole, cefepime, and aminoglycosides are most active agents.
Escherichia coli	Third-generation cephalosporin	First- or second-generation cephalosporin, gentamicin	Extended-spectrum β-lactamase (ESBL) producers should be treated with a carbapenem.
Haemophilus influenzae	Third-generation cephalosporin	β-Lactamase inhibitor combinations, second-generation cephalosporin, trimethoprim-sulfamethoxazole	
Helicobacter pylori	PPI, clarithromycin,	PPI, bismuth,	

	and amoxicillin or metronidazole	tetracycline, and a nitroimidazole	
Klebsiella pneumoniae	Third-generation cephalosporin	First- or second-generation cephalosporin, gentamicin, trimethoprim-sulfamethoxazole	ESBL producers should be treated with a carbapenem.
Legionella	Fluoroquinolone	Erythromycin ± rifampin, doxycycline	
Proteus mirabilis	Ampicillin	First-generation cephalosporin, trimethoprim-sulfamethoxazole	
Other Proteus	Third-generation cephalosporin	β-Lactamase inhibitor combination, aminoglycoside, trimethoprim-sulfamethoxazole	
Pseudomonas aeruginosa	Antipseudomonal penicillin or antispeudomonal cephalosporin) ± aminoglycoside (or quinolone)	Quinolone or imipenem ± aminoglycoside	Most active agents include aminoglycosides, doripenem, imipenem, meropenem, ceftazidime ceftazidime/avibactam, cefepime, ceftolozane/tazobactam, aztreonam, and the extended-spectrum penicillins. Monotherapy is adequate for most pseudomonal infections.
Salmonella typhi	Quinolone	Ceftriaxone	
Serratia marcescens	Third-generation cephalosporin	Trimethoprim-sulfamethoxazole, aminoglycoside	
Shigella	Quinolone	Trimethoprim-sulfamethoxazole, ampicillin	
Stenotrophomonas maltophilia	Trimethoprim-sulfamethoxazole	Ceftazidime, minocycline, β-lactamase inhibitor combination (Timentin)	
Anaerobes			
Bacteroides fragilis	Metronidazole	β-Lactamase inhibitor combinations, penems	Most active agents (95%–100%) include metronidazole, the β-lactamase inhibitor combinations ampicillin-sulbactam, piperacillin-tazobactam, ticarcillin-clavulanic acid, and penems. Clindamycin, cefoxitin, cefotetan, cefmetazole, ceftizoxime have good activity but not to the degree of metronidazole. Aminoglycosides and aztreonam are inactive.
Clostridia difficile	Metronidazole	Vancomycin Fidaxomicin	Oral vancomycin is the drug of choice for severe infection. Fidaxomicin superior to other agents in the

			prevention of relapse
Fusobacterium	Penicillin	Metronidazole, clindamycin	
Other Oropharyngeal			
Prevotella	β-Lactamase inhibitor combination	Metronidazole, clindamycin	
Peptostreptococcus	Penicillin	Clindamycin, cephalosporin	Most β-lactams active (exceptions include aztreonam, nafcillin, ceftazidime)
Other			
Actinomyces israelii	Penicillin	Tetracyclines	
Nocardia	Trimethoprim-sulfamethoxazole	Amikacin, minocycline, imipenem	
Chlamydia trachomatis	Doxycycline	Azithromycin	
Chlamydophila pneumoniae	Doxycycline	Azithromycin, clarithromycin	
Mycoplasma pneumoniae	Doxycycline	Azithromycin, clarithromycin	
Borrelia burgdorferi	Doxycycline	Ampicillin, second- or third-generation cephalosporin	
Treponema pallidum	Penicillin	Doxycycline	

DISK DIFFUSION

The most widely used tests for bacterial susceptibility are the disk diffusion and the broth dilution methods. The disk diffusion (Kirby–Bauer) technique uses an agar plate on which an inoculum of the organism is placed. After inoculation, several antimicrobial-laden disks are placed on the plate, and evidence of bacterial growth is observed after 18 to 24 hours. If the antimicrobial is active against the pathogen, a zone of growth inhibition is observed around the disk. Based on guidelines provided by the Clinical and Laboratory Standards Institute (CLSI), the diameter of inhibition is reported as susceptible, intermediate, or resistant. CLSI zones of inhibitions are determined taking into account known achievable antibacterial concentrations. However, broth dilution determination of minimum inhibitory concentration (see the following text) better links with achievable antibacterial concentrations.

BROTH DILUTION

The broth dilution method involves introducing a bacterial inoculum into several tubes or wells filled with broth. Serial dilutions of antimicrobials (e.g., nafcillin 0.5, 1.0, and 2.0 mcg/mL) are placed in the respective wells. After bacteria are allowed to incubate for 18 to 24 hours, the wells are examined for bacterial growth. If the well is cloudy, bacterial growth has occurred, suggesting resistance to the specific antimicrobial at that concentration. As an example, if bacterial growth is observed with S. aureus at 0.5 mcg/mL of nafcillin but not at 1.0 mcg/mL, then 1.0 mcg/mL would be considered the minimum inhibitory concentration (MIC) for nafcillin against S. aureus.

Similar to the disk diffusion method, the CLSI provides guidelines[17] that also take into account the pharmacokinetic characteristics of an antimicrobial to determine whether the MIC should be reported as susceptible, intermediately susceptible, or resistant. MIC interpretations are both pathogen- and antimicrobial-specific. For example, ciprofloxacin achieves serum concentrations of only 1 to 4 mcg/mL, whereas the fourth-generation cephalosporin, cefepime, achieves peak serum concentrations of 75 to 100 mcg/mL; consequently an MIC of 4.0 mcg/mL for P. aeruginosa would be interpreted by CLSI as resistant to ciprofloxacin but susceptible to cefepime.

Although these tests provide an accurate assessment of in-vitro susceptibility, the time delay (18–24 hours) can hinder streamlining of therapy. An alternative efficient, but more expensive, MIC test is the E test, which uses an antibiotic-laden plastic strip with increasing concentrations of a specific antimicrobial from one end to the other. The strip is placed on an agar plate with the actively growing pathogen. Inhibition of growth observed at specific marks on the strip coincides with the MIC of the organism. Numerous studies have confirmed that the E test is as effective as traditional susceptibility testing. Several automated antimicrobial susceptibility systems are available in the United States, including Phoenix (Becton Dickinson, Franklin Lakes, NJ), Vitek (bioMérieux, Durham, NC), MicroScan WalkAway (Siemens Healthcare Diagnostics, Tarrytown, NY), and Sensititre (Trek Diagnostics, Cleveland, OH). These systems generally use a computerized algorithm for interpreting results and determine the antibiotic MIC for the organism by using specialized decision technology. Two major advantages of automated susceptibility methodologies include a reduction in labor and faster reporting of susceptibility results, potentially leading to the earlier initiation of appropriate antibiotic therapy. Although these represent advantages, disadvantages exist, particularly with cystic fibrosis isolates. Most clinical microbiology laboratories use automated susceptibility testing systems. While these automated antimicrobial susceptibility systems are an improvement over traditional broth dilution and disc diffusion methods, other emerging technologies including PCR and other “next generation” systems are likely to result in more rapid identification of pathogens and their associated antimicrobial susceptibility.

Although susceptibility testing is relatively well standardized for aerobic gram-negative and gram-positive organisms, its utility is not as established for anaerobes[18] and fungi.[19] In general, despite improvements in the standardization of testing in anaerobes, institutions do not routinely perform susceptibility testing for these bacteria. In contrast, susceptibility testing is now available for Candida species, and these in-vitro data have been demonstrated to predict clinical success in the patient care setting.

The consensus of the CLSI and other experts is that anaerobic isolates from blood, bone and joint sources, brain abscesses, empyemic fluid, and other body fluids that are normally sterile should be considered for susceptibility testing. However, in general, these susceptibilities are rarely performed.[18] Progress has been made in developing a standardized test for determining fungal susceptibility, but the primary emphasis has been on the susceptibility of Candida species to azoles in the treatment of candidiasis.[19] Although standardized susceptibility testing for molds is established by the CLSI and other organizations, the correlation with clinical outcome is variable; the best correlation between antifungal susceptibility testing and efficacy lies with the use of azoles in the treatment of disseminated aspergillosis.[20]

DETERMINATION OF ISOLATE PATHOGENICITY

CASE 62-1, QUESTION 7: Serratia marcescens grows from a culture of R.G.'s endotracheal aspirate. How can it be determined whether an isolate represents a true bacterial infection versus colonization or contamination?

A positive culture may represent colonization, contamination, or infection. Colonization indicates that bacteria are present at the site; however, they are not actively causing infection. Poor sampling techniques or inappropriate handling of specimens can result in contamination. Contamination differs from colonization in that these isolates are not truly at the site in question. The S. marcescens growing from R.G. could represent infection, colonization, or contamination. If a suction catheter was used to sample R.G.'s endotracheal aspirate, the infecting organism likely would be cultured; however, other nonpathogenic flora would also appear in the culture medium (colonization). Furthermore, if the sample is not handled aseptically by the clinician or the microbiology laboratory, bacterial contamination is possible.

In summary, culture results do not solely identify true pathogens. In R.G., the Serratia may be a pathogen, contaminant, or colonizer. Nevertheless, considering the severity of R.G.'s illness and his associated respiratory symptoms, treatment directed against this pathogen is necessary.

ANTIMICROBIAL TOXICITIES

CASE 62-1, QUESTION 8: In light of the positive culture for Serratia, his increased respiratory secretions, and a worsening chest radiograph, ventilator-associated pneumonia is likely present. Pending susceptibility results, R.G. is empirically started on imipenem and gentamicin. In review of his patient records, R.G. has no known allergies. Are there equally effective, less toxic options for this patient?

Adverse Effects and Toxicities

Before antimicrobial therapy is started, it is important to elicit an accurate drug and allergy history. When "allergy" has been reported by the patient, it is necessary to determine whether the reaction was intolerance, toxicity, or true allergy. For example, gastric intolerance caused by oral doxycycline is common; however, this adverse effect does not represent an allergic manifestation. Although R.G. has no known allergies, neither imipenem nor gentamicin are optimal choices. Imipenem is associated with seizures, particularly in patients with renal failure and in doses in excess of 50 mg/kg/day. Considering R.G.'s acute onset of renal failure and his history of seizures, other carbapenems, such as meropenem or doripenem, or alternative classes of antibacterials would be preferable. Gentamicin similarly may not be a good choice in R.G. His increased age and declining renal function predispose him to aminoglycoside nephrotoxicity and ototoxicity (cochlear and vestibular).[21] A reasonable recommendation pending susceptibility results would be to discontinue imipenem and gentamicin and treat with meropenem or doripenem with or without a fluoroquinolone. Table 62-8 lists common antibiotics adverse effects and toxicities.

Table 62-8

Antibiotic Adverse Effects and Toxicities

Antibiotics	Side Effects	Comments
β-Lactams (penicillin, cephalosporins, monobactams, penems)	Allergic: anaphylaxis, urticaria, serum sickness, rash, fever	Many patients will have "ampicillin rash" or "β-lactam rash" with no cross-reactivity with any other penicillins/β-lactams. Most commonly observed in patients with concomitant EBV disease. Likelihood of IgE-mediated cross-reactivity between penicillins and cephalosporins approximately 5%–10%. Most recent data strongly suggest minimal IgE cross-reactivity between penicillins and imipenem/meropenem. No IgE cross-reactivity between aztreonam and penicillins.
	Diarrhea	Particularly common with ampicillin, augmentin, ceftriaxone. Antibiotic-associated colitis can occur with most antimicrobials.
	Hematologic: anemia, thrombocytopenia,	Hemolytic anemia more common with higher doses. Antiplatelet activity (inhibition of platelet aggregation) most common with the antipseudomonal penicillins and high serum levels of other β-

	antiplatelet activity, hypothrombinemia	lactams.
		Hypothrombinemia more often associated with those cephalosporins with the methyltetrazolethiol side chain (cefamandole, cefotetan). Reaction preventable and reversible with vitamin K.
	Hepatitis or biliary sludging	Hepatitis most common with oxacillin. Biliary sludging and stones reported with ceftriaxone.
	Phlebitis	
	Seizure activity	Associated with high levels of β-lactams, particularly penicillins and imipenem.
	Potassium load	Penicillin G (K+).
	Nephritis	Occasionally reported for most β-lactams.
	Neutropenia	Nafcillin.
	Disulfiram reaction	Associated with cephalosporins with methyltetrazolethiol side chain (cefamandole, cefotetan).
	Hypotension, nausea	Associated with fast infusion of imipenem.
Aminoglycosides (gentamicin, tobramycin, amikacin, netilmicin)	Nephrotoxicity	Average 10%–15% incidence. Generally reversible, usually occurs after 5–7 days of therapy. Risk factors: dehydration, age, dose, duration, concurrent nephrotoxins, liver disease.
	Ototoxicity	1%–5% incidence, often irreversible. Both cochlear and vestibular toxicity occur.
	Neuromuscular paralysis	Rare, most common with large doses administered via intraperitoneal instillation or in patients with myasthenia gravis.
Macrolides (erythromycin, azithromycin, clarithromycin)	Nausea, vomiting, “burning” stomach, cholestatic jaundice, ototoxicity, prolonged QT interval	Oral administration. Azithromycin and clarithromycin associated with less nausea than erythromycin. Cholestatic jaundice reported for all erythromycin salts, most common with estolate. Ototoxicity most common with high doses in patients with renal or hepatic failure. Torsades de Pointes and increased risk of cardiac death associated with increased QT interval.

Telithromycin	Hepatotoxicity; upper GI	Severe, sometime fatal hepatotoxicity associated with telithromycin.
Clindamycin	Diarrhea	Most common adverse effect. High association with antibiotic-associated colitis.
Tetracyclines (including tigecycline)	Allergic	
	Photosensitivity	
	Drug Interactions	↓ Oral bioavailability with multivalent cations.” similar to that stated in the Quinolones section
	Teeth and bone deposition and discoloration	Avoid in pediatrics (<8 years old), pregnancy, and breast-feeding.
	GI	Upper GI predominates.

	Hepatitis	Primarily in pregnancy or the elderly.
	Renal (azotemia)	Tetracyclines have antianabolic effect and should be avoided in patients with ↓ renal function. Less problematic with doxycycline.
	Vestibular	Associated with minocycline, particularly high doses.
Vancomycin	"Red Man Syndrome": hypotension, flushing	Associated with rapid infusion of vancomycin. More common with increased doses.
	Nephrotoxicity	Reversible nephrotoxicity with high doses or in combination with other nephrotoxins.
	Ototoxicity	Only with receipt of concomitant ototoxins such as aminoglycosides or macrolides.
	Phlebitis	Needs large volume dilution.
Dalfopristin/quinupristin	Phlebitis	Generally requires central line administration.
	Myalgia	Moderate to severe in many patients.
	Increased bilirubin	
Daptomycin	Myalgia	Primarily at high doses and reversible.
Linezolid (Tedizolid)	Thrombocytopenia, neutropenia, anemia, MAO inhibition, neuropathy	Bone marrow suppression and neuropathy duration- and dose-dependent with linezolid. Tedizolid may have less association with bone marrow suppression and neuropathy.
Dalbavancin, Oritavancin, Telavancin	Renal toxicity and prolonged QT with telavancin	
Sulfonamides	GI	Nausea, diarrhea.
	Hepatic	Cholestatic hepatitis, ↑ incidence in HIV.
	Rash Hyperkalemia	Exfoliative dermatitis, Stevens–Johnson syndrome. More common in HIV. Only with trimethoprim (as a component of trimethoprim–sulfamethoxazole).
	Bone marrow	Neutropenia, thrombocytopenia. More common in HIV.
	Kernicterus	Caused by unbound drug in the neonate. Premature liver cannot conjugate bilirubin. Sulfonamide displaces bilirubin from protein, resulting in excessive free bilirubin and kernicterus.
Chloramphenicol	Anemia	Idiosyncratic irreversible aplastic anemia (rare). Reversible dose-related anemia.
	Gray syndrome	Caused by inability of neonates to conjugate chloramphenicol.
Quinolones	GI	Nausea, vomiting, diarrhea.
	Prolonged QT	Moxifloxacin; possibly all quinolones as a class.
	Drug interactions	↓ Oral bioavailability with multivalent cations.
	CNS	Altered mental status, confusion, seizures.
	Cartilage toxicity	Toxic in animal model. Despite this toxicity, appears safe in children including patients with cystic fibrosis.
	Tendonitis or tendon rupture	Common in elderly, renal failure, concomitant glucocorticoids.
Antifungals		
Amphotericin B products	Nephrotoxicity	Common. May depend on patient sodium load. Caution with concomitant nephrotoxins (e.g., aminoglycosides, cyclosporine).

	Hypokalemia	Predictable. Probably caused by renal tubular excretion of potassium. More common in patients receiving concomitant piperacillin–tazobactam.
	Hypomagnesemia	Less commonly observed than hypokalemia.
	Anemia	Long-term adverse effect. Similar to anemia of chronic disease.
Caspofungin, Micafungin, Anidulofungin	Mild LFT increase with concomitant cyclosporine	Anidulofungin is reconstituted with alcohol (about the equivalent of a beer).
Flucytosine	Neutropenia, thrombocytopenia	Secondary to metabolism of flucytosine to fluorouracil. More commonly observed with flucytosine levels >100 mg/mL. More common in patients with HIV.
	Hepatitis	Usually moderate ↑ in LFT. Rarely clinical hepatitis.
Ketoconazole (fluconazole, isavuconazole, itraconazole, posaconazole, voriconazole)	Drug interactions	↓ Oral bioavailability of ketoconazole tablet, and itraconazole capsules with ↑ gastric pH. Azoles are CYP450 substrates and also inhibitors of CYP450 3A4 and other CYP isoenzymes. Voriconazole most likely to be associated with CYP drug interactions
	Hepatitis	Ranges from mild ↑ in LFT to occasional fatal hepatitis.
	Gynecomastia, ↓ libido	More common with high-dose ketoconazole (>400 mg/day). Less common with other azoles.
	Visual disturbance	Unique to voriconazole, particularly first week of therapy.
Antivirals (Excluding Antiretrovirals and Hepatitis Antivirals)		
Acyclovir	Phlebitis	Caused by poor solubility of IV preparation. Reported in 1%–20% of cases.
	Renal failure	Low solubility of acyclovir associated with renal failure. Dehydrated patients, as well as rapid infusions, predispose to toxicity.
	CNS	1% incidence in AIDS. ↑ Incidence with dose in >10 mg/kg/day.
Foscarnet	Nephrotoxicity	Occurs in up to 60% of patients. May be prevented with normal saline bolus before dose. Frequent monitoring of renal function imperative.
	Mineral and electrolyte abnormalities	↑ and ↓ calcium or phosphate may be observed. Hypocalcemia, hypo- and hyperphosphatemia, hypomagnesemia, hypokalemia. ↑ Risk of cardiomyopathy and seizures.
	Anemia	Anemia in 33%; usually manageable with transfusions and discontinuation of foscarnet.
	Nausea, vomiting	
Ganciclovir	Neutropenia, thrombocytopenia	↑ Incidence in AIDS. ↑ Incidence with doses in excess of 10 mg/kg/day.
	Hepatitis	Usually mild to moderate in LFT.
Oseltamavir	Nausea	

AIDS, acquired immunodeficiency syndrome; CNS, central nervous system; EBV, Epstein–Barr virus; GI, gastrointestinal; HIV, human immunodeficiency virus; IV, intravenous; LFT, liver function tests; MAO, monoamine oxidase.

Concomitant Disease States

Concomitant disease states should also be considered in the selection of therapy. As discussed above, older patients with hearing deficits are poor candidates for potentially ototoxic aminoglycoside therapy. Diabetic or kidney transplant patients with candidemia may be better treated with fluconazole or an echinocandin rather than nephrotoxic amphotericin B products. Patients with a preexisting seizure history should not receive imipenem if less toxic therapy can be used. In summary, the toxicologic profile of a drug must be taken into account in the selection of antimicrobial therapy.

ANTIMICROBIAL COSTS OF THERAPY

CASE 62-1, QUESTION 9: What factors should be included in calculating the cost of R.G.'s antimicrobial therapy?

The true cost of antimicrobial therapy is difficult to quantify.[22] Although acquisition cost traditionally has been the primary factor in the overall cost of therapy, drug administration labor costs (i.e., nursing and pharmacy) and the use of IV sets, piggyback bags, and infusion control devices must be included in the analysis. As a result, a drug that must be administered several times daily, such as intravenous penicillin, will incur increased administration costs compared with one, such as ceftriaxone, that requires once-a-day dosing.

Some drugs, such as aminoglycosides, are associated with increased laboratory costs (e.g., aminoglycoside serum concentrations, serum creatinine, and audiometry) that are not required for other agents,[23] such as the third-generation cephalosporins and quinolones. Similarly, drugs with a high potential for misuse or toxicity can be associated with increased costs because of monitoring (e.g., medication use evaluation, pharmacokinetic monitoring). If meropenem with or without ciprofloxacin had been selected for R.G., this therapy would be expected to be associated with relatively few laboratory costs. However, the broad spectrum of activity[24] of these agents, potential for misuse, and development of resistance might, however, result in increased monitoring costs and overall cost to society.

Costs that are difficult to quantitate include those associated with failure of antimicrobial therapy and antimicrobial toxicity. Ineffective or toxic therapy can prolong hospitalization and may require expensive interventions, such as hemodialysis,[23] mechanical ventilation, and intensive care unit admission. The net effect of these latter costs can be significantly greater than the acquisition and administration costs of antimicrobial therapy.

In summary, determining the true cost of antimicrobial therapy is complex.

Acquisition cost, IV bags, infusion controllers, and labor must be incorporated into the analysis. Although they are difficult to estimate, other costs, including antibiotic toxicity and failure of therapy, should also be included.

ROUTE OF ADMINISTRATION

CASE 62-1, QUESTION 10: The Serratia was determined to be susceptible to ciprofloxacin. Oral ciprofloxacin was considered for the treatment of R.G.'s presumed Serratia pneumonia, but the IV route was prescribed. Why is the oral administration of ciprofloxacin reasonable (or unreasonable) in R.G.?

The proper route of antibiotic administration depends on many factors, including the severity of infection, antimicrobial oral bioavailability, and other patient factors. In patients who appear "septic," blood flow often is shunted away from the mesentery and extremities, resulting in unreliable bioavailability from the gastrointestinal (GI) tract or muscles. Consequently, hemodynamically unstable patients should always receive antimicrobials by the IV route to ensure therapeutic antimicrobial levels. Furthermore, some drug interactions with oral agents can result in subtherapeutic serum concentrations (e.g., reduced bioavailability associated with concomitant quinolone and antacid administration and the decreased absorption of itraconazole with concurrent proton-pump inhibitor [PPI] therapy).

R.G. is clinically septic with a possible Serratia pneumonia. Considering his unstable state, the bioavailability of oral ciprofloxacin cannot be guaranteed; thus, he should be treated with IV antimicrobials.

ANTIMICROBIAL DOSING

CASE 62-1, QUESTION 11: What dose of IV ciprofloxacin should be given to R.G.? What factors must be taken into account in determining a proper antimicrobial dose?

The choice of dosing regimen is based on many factors. Table 62-9 provides a guide for the dosing of more commonly administered antimicrobials. Selection of the appropriate dosage should be based on evidence confirming the efficacy of the dosage in the treatment of a specific infection. Patient-specific factors, including weight, site of infection, and route of elimination, must also be considered in dosage selection. The patient's weight is important, particularly for agents with a low therapeutic index (e.g., aminoglycosides, imipenem, and flucytosine); these drugs should be dosed on a milligram per kilogram per day basis. Other agents with a more favorable adverse effect profile, such as cephalosporins, are less likely to require weight-specific dosing in most disease states.

Site of Infection

Site of infection results in different dosage requirements. An uncomplicated urinary tract infection requires lower doses considering the high urinary drug concentrations that are achieved with most renally cleared agents. In contrast, a more serious upper urinary tract infection, such as pyelonephritis, requires increased doses to ensure therapeutic drug levels in tissue and in serum.

Anatomic and Physiologic Barriers

Anatomic and physiologic barriers must also be considered in evaluating a dosing regimen. For example, penetration into cerebrospinal fluid requires high doses to ensure adequate antimicrobial concentrations.[25] Vitreous humor[26] and the prostate gland[27] are additional sites in which therapeutic antimicrobial concentrations are more difficult to achieve.

Route of Elimination

Route of elimination must also be considered in the dosage calculation. In general, antimicrobials are eliminated renally or nonrenally (metabolic or biliary). Renal function can be estimated via 24-hour urine collection or with equations, such as the Cockcroft and Gault equation[28]:

$$\text{Creatinine clearance} = ([140 - \text{age}] \times [\text{weight in kg}])/(72 \times \text{SCr}) \qquad \text{(Eq. 62-1)}$$

Several anti-infectives are eliminated renally (Table 62-9). Most β-lactams are eliminated by the kidney. In contrast, ceftriaxone and most antistaphylococcal penicillins (e.g., nafcillin, oxacillin, and dicloxacillin) are eliminated both renally and nonrenally. Aminoglycosides, vancomycin, acyclovir, and ganciclovir are cleared primarily by the kidney. Thus, dosage adjustment is recommended for these drugs in patients with renal failure (Table 62-9). Because azithromycin, clindamycin, and metronidazole are primarily eliminated by the liver, no dose reduction is required in renal failure for these agents. Using the Cockcroft and Gault equation, R.G.'s age (63 years), weight (70 kg), and current serum creatinine (3.8 mg/dL) results in a calculated creatinine clearance of 14 mL/minute. R.G. normally would be given an IV dosage of ciprofloxacin at 400 mg every 12 hours. His increasing creatinine, however, suggests that his dosage should be decreased to 200 to 300 mg every 12 hours.

Table 62-9

Adult Antimicrobial Dosing Guidelines for Hospitalized Patients (Selected Drugs)

Drug	CrCl > 50 mL/minute	CrCl 10–50 mL/minute	CrCl <10 mL/minute (ESRD not on HD)	Dialysis (HD or CRRT)
Acyclovir	Herpes simplex infections 5 mg/kg/dose IV every 8 hours	5 mg/kg/dose IV every 12–24 hours	2.5 mg/kg IV every 24 hours	HD: 2.5 mg/kg IV ×1 now then 2.5 mg/kg every evening (give after HD on HD days) CRRT: 5 mg/kg every 24 hours
	HSV encephalitis/Herpes zoster 10 mg/kg/dose IV every 8 hours	10 mg/kg/dose IV every 12–24 hours	5 mg/kg IV every 24 hours	HD: 5 mg/kg IV ×1 now then 5 mg/kg every evening (give after HD on HD days) CRRT: 5–10 mg/kg every 12–24 hours
Ampicillin	Meningitis or endovascular infection 2 g IV every 4 hours Uncomplicated infection 2 g IV every 6 hours	2 g IV every 6 hours	1 g IV every 8–12 hours	HD: 1–2 g IV every 12 hours CRRT: 1–2 g IV every 6 hours
Ampicillin/sulbactam	3 g IV every 6 hours	1.5 g IV every 6 hours	1.5 g IV every 12 hours	HD: 1.5–3 g IV every 12 hours CRRT: 1.5 g IV every 6 hours
Aztreonam	2 g IV every 8 hours	2 g IV every 12 hours	1 g IV every 12 hours	HD: 1 g IV ×1 now then 1 g every evening (give after HD on HD days) CRRT: 2 g IV every 12 hours
Cefazolin	Gram negative or complicated Gram	1–2 g IV every 12 hours	1 g IV every 24 hours	HD: 2 g after HD only

	positive 2 g IV every 8 hours Uncomplicated Gram positive 1–2 g IV every 8 hours				CRRT: 2 g IV every 12 hours
Caspofungin Severe hepatic dysfunction: 70 mg LD, then 35 mg IV daily	LD: 70 mg × 1, then 50 mg every 24 hours Increase maintenance dose to 70 mg when given with phenytoin, rifampin, carbamazapine, dexamethasone, nevirapine, efavirenz	No change		No change	No change
Cefepime Less severe infections Febrile neutropenia, meningitis, pseudomonas infections, critically ill patients	>60 mL/minute 2 g IV every 12 hours 2 g IV every 8 hours	30–60 mL/minute 2 g IV every 24 hours 2 g IV every 12 hours	10–30 mL/minute 1 g IV every 24 hours 2 g IV every 24 hours	<10 mL/minute 500 mg IV every 24 hours 1 g IV every 24 hours	HD: 2 g after HD only CRRT: 2 g IV every 12 hours
Ceftazidime	2 g IV every 8 hours	2 g IV every 12–24 hours		500 mg IV every 24 hours	HD: 1 g after HD only CRRT: 2 g IV every 12 hours
Ceftriaxone Meningitis: 2 g every 12 hours Endocarditis and osteomyelitis: 2 g every 24 hours	1 g IV every 24 hours	No change		No change	No change

---

Ciprofloxacin$^{\text{IV-PO}}$ Pseudomonas infections	400 mg IV every 12 hours 500–750 mg PO every 12 hours 400 mg IV every 8 hours 750 mg PO every 12 hours	30–50 mL/minute No change No change	10–30 mL/minute 200–400 mg IV every 12 hours 250–500 mg PO every 12 hours	< 10 mL/minute 200 IV every 12 hours 250 mg PO every 12 hours	HD: 400 mg IV every 24 hours or 500 mg PO every 24 hours (give after HD on HD days) CRRT: 400 mg IV every 12 hours

---

Tobramycin (and gentamicin) Gram negative infection Dose is based on ideal body weight (IBW) except in obese patients or those under their IBW. Use actual body weight if patient weight is less than IBW. Use adjusted body weight if patient is obese. (calculations see below)	For CrCl > 60 mL/minute, not morbidly obese or fluid overloaded, give once daily regimen: 7 mg/kg/dose IV every 24 hours. For those patients not qualifying for once daily dosing, see conventional dosing below.			
For conventional dosing peak and trough levels should be monitored.	>60 mL/minute 1.6 mg/kg IV every 8 hours	40–60 mL/minute 1.2–1.5 mg/kg every 12–24 hours	<20 mL/minute 2 mg/kg loading dose, then follow drug levels	HD: 2 mg/kg IV × 1 then 1 mg/kg IV after HD CRRT: 2 mg/kg IV × 1 then 1.5 mg/kg IV

						every 24 hours
TMP/SMXIV-PO When switching to oral therapy, consider that a single-strength tablet has 80 mg of TMP, a double-strength tablet 160 mg of TMP.	Systemic GNR infections 10 mg TMP/kg/day IV divided every 6–12 hours Pneumocystis pneumonia 15–20 mg TMP/kg/day IV divided every 6–8 hours		5–7.5 mg TMP/kg/day IV divided every 12–24 hours 10–15 mg TMP/kg/day IV divided every 12–24 hours		2.5–5.0 mg TMP/kg IV every 24 hours 5–10 mg TMP/kg IV every 24 hours	HD: 2.5–5 mg TMP/kg/day every 24 hours CRRT: 5–7.5mg TMP/kg/day divided every 12–24 hours
Vancomycin Uncomplicated infections Serious infections	>60 mL/minute 10–15 mg/kg IV every 12 hours[1] 15–20 mg/kg IV every 8–12 hours[2]	40–60 mL/minute 10–15 mg/kg IV every 12–24 hours	20–40 mL/minute 5–10 mg/kg IV every 24 hours	10–20 mL/minute 5–10 mg/kg IV every 24–48 hours	<10 mL/minute 10–15 mg/kg IV loading dose ×1; redose according to serum levels	HD: 15–20 mg/kg load, then 500 mg IV after HD only CRRT: 10–15 mg/kg IV every 24 hours
Round dose to 250 mg, 500 mg, 750 mg, 1 g, 1.25 g, 1.5 g, 1.75 g, or 2 g (maximum 2 g/dose). Trough levels should be obtained within 30 minutes before fourth dose of a new regimen or dosage change. Vancomycin troughs are not recommended in patients in whom anticipated duration of therapy is ≤3 days. [1] For patients with uncomplicated infections requiring vancomycin, trough levels of 10–15 mcg/mL are recommended. [2] For patients with serious infections caused by MRSA (central nervous system infections, endocarditis, ventilator-associated pneumonia, bacteremia, or osteomyelitis), trough levels of 15–20 mcg/mL are recommended.						
VoriconazoleIV-PO	LD = 400 mg every 12 hours × 1 day, then 200 mg every 12 hours (PO)		No change		No change*	No change*
PO should be used when possible, as oral bioavailability >95%. IV dose: LD = 6 mg/kg/dose every 12 hours × 1 day, then 4 mg/kg/dose every 12 hours. *The use of the IV formulation should be avoided in patients with CrCl <50 mL/minute owing to accumulation of IV vehicle and is contraindicated in ESRD and hemodialysis. May require dose adjustment in hepatic dysfunction.						

Doses are those recommended for systemic infections in hospitalized patients commonly treated with these agents for moderate/severe infections. Abstracted in part from doses developed by the UCSF Antibiotic Advisory Subcommittee and the Pharmacy & Therapeutics Committee (updated 6/2015). More mild infection may require decreased doses compared with moderate to severe infection. Dosing guidelines may differ in other institutions.

Estimate of renal function using Cockcroft and Gault equation: CrCl (mL/minute) = (140 – age) × Wt (kg)/72 × SCr (mg/dL) (for females multiply by 0.85). Ideal body weight equation:

Males: IBW = 50 kg + 2.3 kg for each inch over 5 feet.

Females: IBW = 45.5 kg + 2.3 kg for each inch over 5 feet.

Adjusted body weight: ABW = IBW + 0.4 (actual weight - IBW).

CrCl, creatinine clearance; CRRT, continuous renal replacement therapy (assumes an ultrafiltration rate of 2 L/hour with continuous venovenous hemofiltration and an ultrafiltration rate of 1 L/hour and dialysate flow rate of 1 L/hour with continuous venovenous hemodiafiltration and residual native glomerular filtration rate <10 mL/minute); ESRD, end-stage renal disease; HD, intermittent (high-flux) hemodialysis (when administering a daily dose with HD, the drug should be administered after the HD session); HSV, herpes simplex virus; IV, intravenous; IV-PO, high oral bioavailability (consider initiating with or switching to PO therapy when patient tolerating orals); LD, loading dose; MRSA, methicillin-resistant Staphylococcus aureus; PO, by mouth; SCr, serum creatinine.

Although renal function can be approximated with the use of the Cockcroft and Gault equation (or a similar equation), hepatic function is more difficult to evaluate. No standard liver function test (AST, ALT, alkaline phosphatase) has been demonstrated to correlate well with hepatic drug clearance. Some tests, such as PT, INR, and albumin, are markers of hepatic function, but even these tests do not clearly predict drug clearance. Patients receiving hemodialysis or continuous hemofiltration provide additional dosing challenges. Table 62-9 provides dosing recommendations in patients receiving hemodialysis or continuous hemofiltration.

Patient Age

It is important to note that most dosing information is derived from a younger, relatively healthy patient population. It is clear that the very young and the elderly have a decreased ability to clear drugs; thus, dosage requirements for many agents are likely to be decreased in neonatal and geriatric patients.

Fever and Inoculum Effect

The impact of other factors on the selection of an antimicrobial dose is less clear. Fever increases and decreases blood flow to mesenteric, hepatic, and renal organ systems,[29] and it can either increase or decrease drug clearance. Inoculum effect has taken place when higher concentrations of a bacterial inoculum result in an increase in the MIC.[30] As an example, piperacillin may demonstrate an MIC of 8.0 mcg/mL against P. aeruginosa at a concentration of 10^5 colony-forming units/mL (CFU/mL); however, at 10^9 CFU/mL, the MIC may increase to 32 to 64 mcg/mL. This phenomenon is well recognized, particularly with β-lactamase–producing bacteria treated with β-lactam antimicrobials. The more stable the antimicrobial is to β-lactamase, the less the influence of the inoculum effect. Aminoglycosides, quinolones, and imipenem appear to be less affected by the inoculum effect than β-lactams. The inoculum effect probably is most relevant in the treatment of a bacterial abscess, in which extremely high concentrations of bacteria would be expected. As a result, antimicrobials that are more susceptible to the inoculum effect may require increased drug dosages for optimal outcome in the treatment of abscesses.

PHARMACOKINETICS AND PHARMACODYNAMICS

CASE 62-1, QUESTION 12: R.G.'s respiratory status remains unchanged; thus, the ciprofloxacin is discontinued and cefepime and gentamicin are started empirically. The use of a prolonged 3 hour IV infusion of cefepime is being considered in R.G. In addition, the use of single daily dosing of gentamicin is being discussed. What is the rationale for these approaches, and would either be advantageous for R.G.?

β-Lactams, such as cefepime, are not associated with increased bacterial killing with increasing drug concentrations. Pharmacodynamic activity with β-lactams best correlates with the duration of time that antimicrobial levels are maintained above the MIC.[31] The animal model suggests that β-lactam antimicrobials should be dosed such that their serum levels exceed the MIC of the pathogen as long as possible.[31] This observation appears to be most important in the neutropenic model, in which the use of a constant infusion more reliably inhibits bacterial growth compared with traditional intermittent dosing. An additional benefit of the use of constant infusions of β-lactams is that smaller daily doses appear to be as effective as higher doses administered intermittently. Other than this latter outcome, it is unclear, however, whether constant infusions have any distinct advantages or disadvantages compared with usual dosing of β-lactams. The efficacy of quinolones, vancomycin, and daptomycin best correlates with the peak plasma concentration to MIC ratio or area under the curve (AUC) to MIC ratio.[31] In light of this pharmacodynamic principle, it is possible that ciprofloxacin was underdosed in this patient, contributing to the therapeutic failure, particularly if the MIC was in the upper range of susceptibility for this agent.

Aminoglycosides traditionally have been administered every 8 to 12 hours to achieve peak serum gentamicin levels of 5 to 8 mcg/mL to ensure efficacy in the treatment of serious gram-negative infection.[32],[33] Gentamicin troughs of greater than 2 mcg/mL have been associated with an increased risk for nephrotoxicity.[33],[34] These studies attempting to correlate efficacy and toxicity with serum levels and the association of peaks or troughs with clinical outcomes have been questioned.[21] Vancomycin troughs of 5 to 10 mcg/mL have been traditionally recommended[35],[36]; however, current recommendations suggest higher troughs (10–20 mcg/mL) depending on the pathogen, site of infection, and severity of illness.[37]

Several antimicrobials (e.g., aminoglycosides) have been associated with a pharmacodynamic phenomenon known as a post-antibiotic effect (PAE). PAE is delayed regrowth of bacteria after exposure to an antibiotic[31],[38] (i.e., continued suppression of normal growth in the absence of antibiotic levels above the MIC of the organism). As an example, if P. aeruginosa is cultured in broth, it will multiply to a concentration of 10^9 CFU/mL. If piperacillin is added in a concentration above the MIC for the organism, a reduction in the bacterial concentration is observed. As described previously, a β-lactam antibiotic should be present in concentrations above the MIC to optimize its time-dependent killing. When piperacillin is removed from the broth, immediate bacterial growth takes place. If the above experiment is repeated with gentamicin, a reduction in bacterial CFU is observed. In contrast to that observed with β-lactam antibiotics, if the gentamicin is removed from the system, a lag period of 2 to 6 hours takes place before characteristic bacterial growth occurs. This lag period is defined as the PAE. A PAE has also been observed with quinolones and imipenem against gram-negative bacteria. Although most β-lactam antibiotics, such as antipseudomonal penicillins or cephalosporins, do not exhibit PAE with gram-negative organisms, PAE has been demonstrated with β-lactam with gram-positive pathogens such as S. aureus.

Once-Daily Dosing of Aminoglycosides

As a result of PAE and other pharmacodynamic factors, certain antimicrobials may be dosed less frequently. The greatest clinical experience has been with the aminoglycosides in the treatment of gram-negative infection.[39],[40] Earlier data suggested that the maximal aminoglycoside peak level to MIC ratio correlates well with clinical response. Thus, the higher the achievable peak, the greater likelihood of a favorable outcome. Consequently, greater, less frequent doses of aminoglycosides should work at least as well as the more traditional lower, more frequent doses. Once-daily dosing of aminoglycosides in the treatment of gram-negative infection is as efficacious as traditional multiple daily dosing.[21]

Single daily dosing of aminoglycosides has been investigated primarily in patients with normal renal function, and few critically ill patients have been treated with this nontraditional regimen.

Thus, patients in septic shock are less clear candidates for once-daily dosing. The utility and proper timing of serum aminoglycoside concentrations and association with clinical outcomes are debatable with nontraditional once-daily aminoglycosides.

In summary, the use of a prolonged IV infusion of cefepime is possible in R.G., but the benefit of this mode of administration is not clear. Considering the severity of R.G.'s infection and his elevated serum creatinine level, he is not a candidate for single daily dosing of aminoglycosides (i.e., 5–6 mg/kg every 24 hours). Independent of the aminoglycoside-associated PAE, his current renal function requires a reduced gentamicin dose to treat his infection.

Antimicrobial Protein Binding

CASE 62-1, QUESTION 13: Ceftriaxone (Rocephin), rather than cefepime, is being considered for the treatment of R.G.'s infection. Ceftriaxone is more highly protein bound than cefepime. Why is protein binding important in the selection of therapy?

Free (i.e., unbound) rather than total drug levels are best correlated with antimicrobial activity,[41] and the degree of protein binding may have important clinical consequences in some patients. Chambers et al.[42] reported treatment failures with the highly protein-bound cefonicid (98% protein bound) in patients with endocarditis caused by S. aureus. Despite achievable serum drug concentrations well above the MIC of the organism, breakthrough bacteremia occurred in three of four patients. Although total drug concentrations greatly exceeded the MIC of the pathogen, free concentrations were consistently below the level necessary to inhibit bacterial growth. Similar experiences have been reported with daptomycin (90% to 93% protein bound).[43] Thus, clinical cure appears to be more likely if unbound antibiotic concentrations exceed the MIC of the infecting organism. Although ceftriaxone is 85% to 90% protein bound, the free concentrations probably remain far above the MIC of the Serratia. Therefore, protein-binding considerations are unlikely to be important in the treatment of R.G.'s infection.

ANTIMICROBIAL FAILURE

Antibiotic-Specific Factors

CASE 62-1, QUESTION 14: Despite "appropriate" treatment, R.G. is unresponsive to antimicrobial therapy. What antibiotic-specific factors may contribute to "antimicrobial failure"?

Antimicrobials may fail for various reasons, including patient-specific host factors, drug or dosage selection, and concomitant disease states. One of the most common reasons for antimicrobial failure is drug resistance.[44–46] Several clinically important pathogens have been associated with emergence of resistance during the past decade, including M. tuberculosis,[47] enterococci,[48] gram-negative rods,[44] S. aureus,[49] S. pneumoniae,[50] and others. Of particular concern is the isolation of glycopeptide-resistant S. aureus,[49] and multidrug-resistant Acinetobacter and Pseudomonas.[51] Development of resistance during therapy, although less common than initial intrinsic resistance, may also account for failure to respond to therapy. Organisms that produce extended-spectrum β-lactamase or amp C β-lactamases may be unresponsive to β-lactam therapy despite associated in-vitro susceptibility.[52]

Superinfection may also play a role in the unsuccessful treatment of infection. Superinfection has taken place when a new pathogen resistant to the current antimicrobial regimen is isolated. If R.G.'s ceftriaxone-treated Serratia pneumonia subsequently worsens and a tracheal aspirate returns positive for P. aeruginosa, then supercolonization and, perhaps, superinfection have occurred.

Combination Therapy

Most infections can be treated with monotherapy (e.g., an E. coli wound infection is treatable with a cephalosporin). Some infections, however, require two-drug therapy, including most cases of enterococcal endocarditis and perhaps certain P. aeruginosa infections. Hilf et al.[53] studied 200 consecutive patients with P. aeruginosa bacteremia and demonstrated a 47% mortality in those receiving monotherapy (antipseudomonal β-lactam or aminoglycoside) versus 27% in those in whom two-drug therapy was used. Thus, monotherapy appeared to contribute to antimicrobial failure in this specific study.

In contrast to the findings of the previous trial, almost all later investigations do not support the use of two drugs over monotherapy in the treatment of serious gram-negative infection, including P. aeruginosa.[54–56] An exception to this rule is bacteremia caused by P. aeruginosa in neutropenic patients.

If two antimicrobials are used in the treatment of infection, one of three sequelae will result: indifference, synergism, or antagonism.[57] Indifference occurs when the antimicrobial effect of drug A plus that of drug B equals the anticipated sum activity of the two drugs. Although numerous definitions exist, synergism generally occurs when the addition of drug A to drug B results in a total antibiotic activity greater than the expected sum of the two agents. Antagonism occurs if the addition of drug A to drug B results in a combined activity less than the sum of drug A plus drug B. An example of antagonism is the combination of imipenem with a less β-lactamase–stable β-lactam, such as piperacillin.[58] If P. aeruginosa is exposed to imipenem and piperacillin, the imipenem induces the organism to produce increased β-lactamase. Imipenem is remarkably β-lactamase stable and is not degraded by this β-lactamase. In direct contrast, piperacillin is easily degraded by the β-lactamase. Thus, imipenem antagonized the effectiveness of piperacillin. Antagonism is not unique to antibacterials; itraconazole may antagonize amphotericin B in the treatment of certain fungal infections.[59]

Pharmacologic Factors

CASE 62-1, QUESTION 15: What pharmacologic or pharmaceutic factors may be implicated in failure of therapy?

Subtherapeutic dosing regimens are commonplace, particularly for agents with a low therapeutic index, such as the aminoglycosides. For example, a serious gram-negative pneumonia may not respond to aminoglycoside therapy if the achievable peak gentamicin serum levels are only 3 to 4 mcg/mL.[21],[32] Considering that only 20%

to 30% of the aminoglycoside penetrates from serum into bronchial secretions, only 0.5 to 1.0 mcg/mL may exist at the site of infection,[60] a level that may be inadequate to treat pneumonia. Another example of dosing contributing to antimicrobial failure centers on the use of loading doses. Aminoglycosides or vancomycin should be initiated with a loading dose, particularly in patients with renal failure. If the clinician neglects to use a loading dose, it may take several days before a therapeutic level is achieved. As described previously, yet another reason for subtherapeutic antimicrobial levels and potential drug failure is reduced oral absorption secondary to drug interactions (e.g., concomitant oral ciprofloxacin with antacids or iron).

An emerging problem relates to the use of vancomycin in the treatment of serious methicillin-resistant S. aureus (MRSA) infection. By CLSI standards, an isolate of MRSA with an MIC of 2 mcg/mL is considered susceptible. Current vancomycin dosing schemes are designed to achieve an AUC/MIC ratio of ≥400 to ensure maximal efficacy. However, a meta-analysis of patients with S. aureus bacteremia demonstrated no differences in the risk of death when comparing patients with S. aureus exhibiting high-vancomycin MIC (≥1.5 mg/L) to those with low-vancomycin MIC (<1.5 mg/L).[61] The infection site also potentially contributes to antimicrobial failure. Most antimicrobials concentrate in the urine, resulting in therapeutic levels even with low doses. In some infections, such as meningitis, prostatitis, and endophthalmitis, antimicrobial penetration to the site of infection may be inadequate. Agents that penetrate well into these sites are associated with a more favorable outcome.

Another potential reason for antimicrobial failure is inadequate therapy duration. A woman with a first-time uncomplicated cystitis may respond adequately to a 3-day course of an antibiotic. In contrast, patients with recurrent urinary tract infections are not candidates for this short course of therapy, however, and failure would be expected with only 3 days of therapy.

Host Factors

CASE 62-1, QUESTION 16: What host factors may contribute to the failure of antimicrobial therapy?

Several host factors may limit the ability of an antibiotic to cure infection. Infection of prosthetic material (e.g., IV catheters, orthopedic prostheses, mechanical cardiac valves, and vascular grafts) is difficult to eradicate without removal of the hardware. In most cases, surgical intervention is necessary. To treat R.G.'s IV catheter infection adequately, removal of his central intravenous catheter would be optimal. Similar to removal of prostheses, large undrained abscesses are difficult, if not impossible, to treat with antimicrobial therapy. These infections generally require surgical drainage for successful outcome.

Diabetic foot ulcer cellulitis may not respond adequately to antimicrobial therapy. Reasons for antimicrobial failure in patients with diabetes include poor wound healing and reduced delivery of antibiotics to the infection site.

Immune status, particularly neutropenia or lymphocytopenia, also affects the outcome in the treatment of infection. Profoundly, neutropenic patients with disseminated Aspergillus infections are unlikely to respond to even the most appropriate antifungal therapy. Similarly, patients with AIDS, who have low CD4 lymphocyte counts, cannot eradicate various infections, including those caused by cytomegalovirus, atypical mycobacteria, and cryptococci.

Once these factors have been eliminated as causes for antimicrobial failure, noninfectious sources must be ruled out. As discussed, malignancy, autoimmune disease, drug fever, and other diseases must be evaluated.

CASE 62-1, QUESTION 17: Other than initiation of adequate antimicrobial therapy, what adjunct measures can be considered in this patient with septic shock?

The 2013 Surviving Sepsis Campaign: International Guidelines for Management of Severe Sepsis and Septic Shock consultants developed key recommendations toward the early goal-directed resuscitation of the septic patient.[62] These recommendations include the use of “sepsis bundles”, i.e., multiple interventions taking place at the same time. Key recommended adjuncts include administration of broad-spectrum antibiotics within 1 hour of diagnosis of septic shock, administration of either crystalloid or colloid fluid resuscitation, and norepinephrine or dopamine to maintain mean arterial pressure of at least 65 mm Hg. In addition, stress-dose steroid therapy can be given to those patients whose blood pressure is poorly responsive to fluid resuscitation and vasopressors. While one might expect improved survival with adherence to such guidelines, the results have been mixed. A large meta-analysis evaluated the influence of performance improvement programs regarding compliance with sepsis bundles. These programs have been found to be associated with increased adherence to resuscitation and management sepsis bundles and with reduced mortality in patients with sepsis, severe sepsis, or septic shock.[63] In contrast, in patients with septic shock who were identified early and received intravenous antibiotics and adequate fluid resuscitation, hemodynamic management according to a strict early goal-directed therapy protocol did not lead to an improvement in outcome.[64]

Antimicrobial Prophylaxis for Surgical Procedures

Daniel J. G. Thirion

	CORE PRINCIPLES	CHAPTER CASES
①	Assessment of the risk of infection is based on patient and procedure risk factors.	**Case 63-1 (Question 1)**
②	Surgical antibiotic prophylaxis is indicated for patients at high risk of infection or in those at high risk of complications from postoperative infection.	**Case 63-2 (Question 1),** **Case 63-4 (Question 1)**
③	The choice of agent is based on the most likely pathogen associated with surgical site infection. Institutional patterns of pathogens, their resistance profiles, and antibiotic cost impact agent selection.	**Case 63-2 (Question 2),** **Case 63-6 (Questions 1, 2),** **Case 63-7 (Question 1),** **Case 63-8 (Question 1)**
④	To maximize the benefit of prophylaxis, antibiotic administration should be completed within 1 hour before incision to achieve adequate drug levels at the surgical site.	**Case 63-2 (Question 3),** **Case 63-5 (Question 1)**
⑤	Intravenous administration is most commonly used. Coadministration of an oral regimen is recommended in colorectal surgery.	
⑥	Antimicrobials with shorter half-lives may require administration of an additional intraoperative dose in prolonged surgical cases.	**Case 63-2 (Question 4)**
⑦	Single-dose preoperative prophylaxis is sufficient for most surgical procedures.	**Case 63-3 (Questions 1, 2),** **Case 63-5 (Question 1)**
⑧	Continuation of postoperative prophylaxis for up to 24 hours in cardiac surgery has been recommended by some professional organizations.	**Case 63-4 (Question 1)**
⑨	Continuation of prophylaxis beyond these time frames is not associated with improved outcomes and increases the risk of superinfections, emergence of resistance, adverse effects, and cost.	**Case 63-8 (Question 2)**
⑩	Surgical site infections are classified as superficial or deep incisional and usually occur within 30 days after the surgical procedure. Deep organ or space infections can occur up to several months after surgery and up to a year after implantation of prosthetic material.	**Case 63-5 (Question 2)**
⑪	Continuous quality improvement is critical in the prevention of surgical	**Case 63-9 (Question 1)**

infection and should be overseen by a multidisciplinary team.

Surgical site infection (SSI) occurs when a pathogenic organism multiplies in a surgical wound, leading to local and sometimes systemic signs and symptoms. Infections complicate surgical procedures in about 2% to 5% of cases but can be as high as 20%, depending on the surgical procedure and the patient.[1–3] Surgical site infections are the most common health-care associated infections.[2] They put patients at risk of death, increase morbidity, extend the duration of hospitalization,[4] and are associated with an annual cost of $3.5 billion to $10 billion in the United States.[5],[6]

Prophylactic antibiotics are widely used in surgical procedures and account for substantial antibiotic use in many hospitals.[7] The purpose of surgical antibiotic prophylaxis is to reduce the prevalence of postoperative wound infection. Appropriate use of prophylactic antimicrobial agents results in decreased patient morbidity and hospitalization costs for many surgical procedures.[8] However, the benefits of prophylaxis are questionable for surgical procedures at low risk of infection (e.g., urologic operations in patients with sterile urine).[9] Consequently, inappropriate or indiscriminate use of prophylactic antibiotics can expose the patient to unnecessary risk of drug toxicity and superinfections, promotes the selection of resistant organisms, and increases cost.[10–12]

RISK FACTORS FOR INFECTION

CASE 63-1

QUESTION 1: C.P., a 78-year-old woman with osteoarthritis, is hospitalized for an elective hip surgery. She is 165 cm tall, weighs 90 kg, and is a nonsmoker. The surgery is planned to last within the usual time frame of the operation, which is about 1 to 2 hours. What is the risk of infection following surgery for her?

The likelihood for development of postoperative site infection is related to the degree of bacterial contamination during surgery, the virulence of the infecting organism, and host defenses. Risk factors for postoperative site infection can be classified according to procedure-specific factors and patient characteristics.[13–15] Bacterial contamination can occur from exogenous sources (e.g., the operative team, instruments, airborne organisms) or from endogenous sources (e.g., the patient's microflora of the skin, respiratory, genitourinary, or gastrointestinal [GI] tract).[16] Procedure-specific factors such as the surgeon's experience and technique, the duration of the procedure, and the operating room environment have important influence on SSI rates. Infection control procedures to minimize all sources of bacterial contamination, including patient and surgical team preparation, operative technique, and incision care, are compiled in Centers for Disease Control and Prevention guidelines for surgical site infection.[17]

The risk of postoperative wound infection is influenced by host factors, such as extremes of age, obesity, tobacco use, malnutrition, and comorbid states, including diabetes mellitus, glycemic control in diabetic patients, remote infection, ischemia, oxygenation and body temperature during the procedure, colonization with microorganisms, immune status, and immunosuppressive therapy.[9]

Measuring and predicting risk of infection determines which patients should receive antibiotic prophylaxis. The Centers for Disease Control and Prevention Study on the Efficacy of Nosocomial Infection Control (SENIC) developed an index that included the level of wound contamination and three other criteria based on procedure-related and patient-related factors.[18] Modification of this tool has led to the National Nosocomial Infection Surveillance (NNIS) System risk index that takes into account the patient's preoperative assessment (American Society of Anesthesiologists Assessment),[19] the level of contamination of the procedure, the duration of the procedure, and the use of a laparoscope.[13] This last criterion was added because of the associated decreased incidence of infection with the introduction of laparoscopic procedures. Indexes like these are particularly useful for comparison of performance among institutions and public reporting.

Based on these risk factors for infection, the decision whether a given patient should receive antimicrobial prophylaxis depends on a number of factors. Antimicrobial prophylaxis should be given for surgical procedures (a) with a high rate of infection (i.e., clean-contaminated or contaminated procedures), or (b) involving the implantation of prosthetic materials, or (c) in which an infection would have catastrophic consequences.[9] A widely used surgical wound classification system to assist in this decision-making process follows.

C.P. is at relatively low risk of infection. There is only one point as attributed to the NNIS score because she will undergo a clean surgery within the average time frame. Her American Society of Anesthesiologists score is 2, being known with mild systemic disease (obese, rheumatoid arthritis, age over 60).

CLASSIFICATION OF SURGICAL SITE INFECTIONS

From 1960 to 1964, the National Academy of Sciences National Research Council conducted a landmark study of surgical site infections and formulated a widely used standard classification based on the risk of intraoperative bacterial contamination (Table 63-1).[20] Current recommendations for surgical prophylaxis pertain to clean surgeries at high risk of complications and/or involving implantation of prosthetic material, clean-contaminated surgeries, and select contaminated wounds. Antimicrobial therapy for dirty surgeries in which infection already is established is considered treatment instead of prophylaxis and is not discussed further in this chapter. Table 63-2 lists suspected pathogens and recommendations for site-specific prophylactic antimicrobial regimens; a detailed examination of clinical trials supporting these recommendations is presented elsewhere.[9]

Table 63-1

National Research Council Wound Classification

Classification	Criteria	Infection Rate (%) without Antibiotic Prophylaxis	Infection Rate (%) with Antibiotic Prophylaxis
Clean	No acute inflammation or entry into GI, respiratory, GU, or biliary tracts; no break in aseptic technique occurs; wounds primarily closed	>5	0.8
Clean-contaminated	Elective, controlled opening of GI, respiratory, biliary, or GU tracts without significant spillage; clean wounds with major break in sterile technique	>10	1.3
Contaminated	Penetrating trauma (<4 hours old); major technique break or major spillage from GI tract; acute, non-purulent inflammation	15–20	10.2
Dirty	Penetrating trauma (>4 hours old); purulence or abscess (active infectious process); preoperative perforation of viscera	30–100	Therapeutic antibiotics

GI, gastrointestinal; GU, genitourinary.

Table 63-2

Suggested Prophylactic Antimicrobial Regimens for Surgical Procedures

Procedure	Predominant Organisms	Recommended Agent(s)[a],[b]	Alternative Agents[a],[b]
Clean			
Neurosurgery	Staphylococcus aureus,	Cefazolin	Clindamycin, vancomycin

	Staphylococcus epidermidis		
Cardiac (all with sternotomy, cardiopulmonary bypass, pacemaker, and automated defibrillator placement)	S. aureus, S. epidermidis	Cefazolin	Cefuroxime, clindamycin, vancomycin
Thoracic	S. aureus, S. epidermidis, gram-negative enterics	Cefazolin	Ampicillin–sulbactam, clindamycin, vancomycin
Vascular (aortic resection, groin incision, prosthesis)	S. aureus, S. epidermidis, gram-negative enterics	Cefazolin	Clindamycin, vancomycin
Orthopedic (total joint replacement, internal fixation of fractures)	S. aureus, S. epidermidis	Cefazolin	Clindamycin, vancomycin
Clean-Contaminated			
Head and neck (involving incisions through mucosa)	S. aureus, oral anaerobes, streptococci	Cefazolin + metronidazole	Ampicillin–sulbactam, clindamycin
Gastroduodenal (only for procedures entering the stomach)	Gram-negative enterics, S. aureus, mouth flora	Cefazolin	Clindamycin or vancomycin + aminoglycoside
Appendectomy (uncomplicated)	Gram-negative enterics, anaerobes (Bacteroides fragilis), enterococci	Cefoxitin	Cefazolin + metronidazole, metronidazole + aminoglycoside
Biliary tract (only for high-risk procedures)	Gram-negative enterics, enterococci, Clostridia	Cefazolin	Cefoxitin, ampicillin–sulbactam, clindamycin + aminoglycoside
Colorectal	Gram-negative enterics, anaerobes (B. fragilis), enterococci	Cefazolin + metronidazole	Ampicillin–sulbactam, metronidazole + aminoglycoside
Cesarean section	Group B streptococci, enterococci, anaerobes, gram-negative enterics	Cefazolin	Clindamycin + aminoglycoside
Hysterectomy	Group B streptococci, enterococci, anaerobes, gram-negative enterics	Cefazolin	Clindamycin or vancomycin + aminoglycoside
Genitourinary (only for high-risk procedures)	Gram-negative enterics, enterococci	Fluoroquinolone	Aminoglycoside + clindamycin

[a] Dose of antibiotics are ampicillin–sulbactam 3 g, cefazolin 2 g in patients weighing up to 120 kg and 3 g if weighing more than 120 kg, cefuroxime 1.5 g, cefoxitin 2 g, ciprofloxacin 400 mg, clindamycin 900 mg, gentamicin 5 mg/kg based on dosing weight and single dose, levofloxacin 500 mg, metronidazole 500 mg, vancomycin 15 mg/kg.

[b] Vancomycin and ciprofloxacin require longer infusion times and should be administered within 2 hours before surgery.

PRINCIPLES OF SURGICAL ANTIMICROBIAL

PROPHYLAXIS

Decision to Use Antimicrobial Prophylaxis

CASE 63-2

QUESTION 1: M.R., a 72-year-old woman, is admitted to the hospital with severe abdominal pain, nausea and vomiting, and temperature of 39.3°C. A diagnosis of acute cholecystitis is made, and M.R. is scheduled for biliary tract surgery (cholecystectomy). Why is antimicrobial prophylaxis warranted for M.R.?

Biliary tract surgery is considered a clean-contaminated procedure and, therefore, carries a risk of surgical wound infection approaching 10% (Tables 63-1 and 63-2). Prophylaxis for biliary tract surgery is limited to high-risk categories, which include obesity, age older than 70 years, diabetes mellitus, acute cholecystitis, obstructive jaundice, common duct stones, emergency procedures, pregnancy, immunosuppression, nonfunctioning gallbladder, or insertion of prosthetic device.[9] Prophylaxis is not recommended for low-risk procedures such as elective laparoscopic cholecystectomy. Thus, prophylaxis is warranted in M.R., who falls into at least two high-risk categories (age older than 70 years and acute cholecystitis).

CASE 63-2, QUESTION 2: An order for intravenous (IV) cefazolin 2 g on call to the operating room (OR) is written for M.R. Why is this an appropriate (or inappropriate) antibiotic selection?

The selected prophylactic agent should be directed against likely infecting organisms (Table 63-2) but need not eradicate every potential pathogen. In general, pathogens associated with infection originate from the skin or the associated structures contiguous to the regions involved in the surgical procedure. Cefazolin has been proved effective for most surgical procedures, including biliary tract surgery, given that the goal of prophylaxis is to decrease bacterial counts below critical levels necessary to cause infection. Broad-spectrum agents, such as third-generation cephalosporins, should be avoided for prophylaxis because they are no more effective than cefazolin and may alter microbial flora, increasing the emergence of microbial resistance to these otherwise valuable agents. The 2 g cefazolin dose is appropriate for all adults weighing less than 120 kg and should be 3 g for patients over 120 kg.

Timing of Antimicrobial Administration

CASE 63-2, QUESTION 3: Why is the administration time for this antimicrobial appropriate (or inappropriate) for M.R.?

Classic animal studies conducted by Burke[21] and others[22] clearly demonstrated the need for therapeutic antibiotic concentrations in the bloodstream and in vulnerable tissue at the time of wound contamination. Bacteria were most likely to enter the tissue beginning with the initial surgical incision and continuing until the wound was closed; antibiotics administered more than 3 hours after bacterial contamination were ineffective in decreasing the rate of wound infection.[21],[22] This 2- to 3-hour period after the surgical incision was deemed the "effective" or "decisive" period for prophylaxis, when the animal's wound was most susceptible to the beneficial effects of the antibiotic. This decisive period for administration of prophylactic antibiotics has been confirmed in humans to be somewhere within 2 hours before incision as compared to earlier administration or anytime after incision.[23–26] The precise window for optimal outcomes is still being investigated.[27]

For maximal efficacy, an antibiotic should be present in therapeutic concentrations at the incision site as early as possible during the decisive period and continuing until the wound is closed. Because an antibiotic administered postoperatively cannot achieve therapeutic concentrations during the decisive period, postoperative administration does not prevent postoperative wound infections, and infection rates are similar to those in patients who receive no antibiotics.[28]

Consequently, prophylactic antibiotics should be administered before the surgical procedure in the operative suite.[9] Prophylactic antibiotics are most effective when given within the 1-hour window before surgical incision; rates of infection increase significantly if antibiotics are administered more than 1 hour before incision or postoperatively.[25],[26] Administration of vancomycin and fluoroquinolones should begin within 120 minutes before surgical incision because of the prolonged infusion times required for these drugs. If a tourniquet is required to control blood flow to a limb during surgery, the evidence is insufficient to recommend administering the dose before or after inflation of the tourniquet.[16]

The "on-call" prescribing practice for surgical prophylaxis, as with M.R., has fallen into disfavor because the time between antibiotic administration and the actual incision may exceed 1 hour. This delay may result in subtherapeutic antibiotic concentrations during the decisive period.[9],[29] M.R.'s cefazolin should be ordered preoperatively and should be administered in the OR within 1 hour of the surgical incision.

CASE 63-2, QUESTION 4: Will M.R. require a second dose of cefazolin during the surgical procedure?

The duration of the surgical procedure and the half-life of the administered antibiotic should be considered when determining the need for an additional intraoperative dose. The longer the duration of the surgical procedure, particularly with short half-life antibacterials, the greater the incidence of postoperative infection.[24],[30],[31] Cefazolin, with a half-life of approximately 1.8 hours, is effective in a single preoperative dose for most surgical procedures. For prolonged procedures, or those with major blood loss,[32],[33] additional intraoperative doses should be administered every 2 half-lives of the drug.[9] M.R. should require an additional intraoperative cefazolin dose only if the surgical procedure is prolonged (>4 hours).

Route of Administration

CASE 63-3

QUESTION 1: G.B., a 55-year-old woman recently diagnosed with carcinoma of the large bowel, is admitted to the hospital for an elective colorectal surgical resection; the surgery is expected to last 5 hours. Physical examination reveals a cachectic woman with a 9-kg weight loss during the previous 3 months (current weight, 60 kg). Increased frequency of bowel movements and chronic fatigue are noted; all other systems are normal. Laboratory data include the following:

Hemoglobin (Hgb), 10.4 g/dL (normal, 12.1–15.3 g/dL; SI units, 104 g/L)
Hematocrit (Hct), 29.7% (normal, 36%–45%; SI units, 0.297)
Prothrombin time (PT), 15 seconds (normal, 10–13 seconds)

Stool guaiac is positive. Vital signs are within normal limits. G.B. is taking no medications and has no history of drug allergies. The following orders are written to begin at home on the day before surgery: (a) clear liquid diet; (b) mechanical bowel cleansing with polyethylene glycol-electrolyte lavage solution (CoLYTE, GoLYTELY); and (c) neomycin sulfate 1 g and erythromycin 1 g orally (PO) at 1, 2, and 11 pm. Comment on the appropriateness of the oral route of administration of antibiotic prophylaxis for G.B.

In general, oral administration of surgical antimicrobial prophylaxis is not recommended because of unreliable or poor absorption of oral agents in the anesthetized bowel. Oral nonabsorbable agents, however, function effectively as GI decontaminants because high intraluminal drug concentrations are sufficient to decrease bacterial counts.[34] The concentration of bacteria in the colon may approach 10^{16} bacteria/µL, and colorectal procedures, such as the one G.B. will undergo, carry a relatively high risk of postoperative infection. Antimicrobial regimens with activity against aerobic and anaerobic bacterial fecal flora (Escherichia coli and other Enterobacteriaceae and Bacteroides fragilis) are effective in preventing postoperative wound infections.[34]

A widely used oral antimicrobial regimen is 1 g each of the nonabsorbable antibiotics neomycin sulfate (for gram-negative aerobes) and erythromycin base (for anaerobes), given 1 day before surgery at the times indicated for G.B.[35] Mechanical bowel cleansing, such as with polyethylene glycol-electrolyte or sodium phosphate lavage solution, precede administration of this regimen; the purpose of bowel purging is to evacuate the colonic contents as completely as possible to decrease colonic bacterial counts. Effective oral alternatives to neomycin plus erythromycin include metronidazole with or without neomycin or with kanamycin, or kanamycin plus erythromycin[36],[37]; however, clinical situations warranting the use of such alternatives over the well-established neomycin–erythromycin regimen are practically nonexistent. Thus, the regimen selected for G.B. is highly appropriate.

CASE 63-3, QUESTION 2: The surgical resident has canceled the oral neomycin–erythromycin bowel regimen for G.B. Instead, he orders cefoxitin (Mefoxin) 1 g IV preoperatively. Is this change in therapy an effective and rational choice for G.B.?

Numerous parenteral regimens, specifically with agents that possess both aerobic and anaerobic activity, are effective as surgical prophylaxis in colorectal procedures. The second-generation cephalosporins with significant anaerobic activity (e.g., cefoxitin) are superior to first-generation cephalosporins, which lack sufficient anaerobic activity.[38] Mechanical bowel preparation with the combination of oral and intravenous antibiotics is superior to oral or intravenous agents alone.[35]

Also, the cefoxitin order for G.B. would be unacceptable if the surgery lasts longer than 3.5 hours (the relatively short half-life of cefoxitin could be associated with inadequate antibacterial levels and predispose her to infection).[39] For prolonged procedures (>3 hours) such as anticipated for G.B., an alternative agent with a longer half-life, such as ertapenem, or a second dose of cefoxitin should be considered. Ertapenem has been found to be superior to cefotetan in preventing infection after colorectal surgery.[40] This improved efficacy may be because of the long half-life or broader antibacterial activity.[41] Whereas ertapenem may offer certain advantages as a prophylactic antibiotic, its use in this indication is discouraged by most clinicians.[9] Although unproven, the potential impact of widespread ertapenem utilization on subsequent carbapenem resistance is of hypothetical concern.[42] The increased acquisition cost of ertapenem also needs to be considered. Thus, for G.B., the importance of redosing intravenous regimens with short half-lives in prolonged surgery should be stressed to the resident.

CASE 63-3, QUESTION 3: The surgical resident has reconsidered the cefoxitin order and decides to prescribe both the oral and parenteral prophylactic regimens for G.B. Will the combination significantly reduce the rate of postoperative wound infection compared with either regimen administered singly?

Coadministration of an oral regimen followed by a parenteral antibiotic prior to incision is equivalent or superior to administration of either regimen alone in reducing infection rates.[35],[43] Oral antibiotics, however, have only been evaluated in combination with mechanical bowel preparation. The optimal agents and regimens as prophylaxis in colorectal surgery remain to be adequately determined. For now, combination of oral and parenteral antimicrobial prophylaxis with mechanical bowel preparation is recommended for colorectal surgery.[9]

Duration of Administration

CASE 63-4

QUESTION 1: L.G., a 28-year-old man with a history of rheumatic heart disease, has a 12-year history of a heart murmur consistent with mild mitral stenosis and mitral regurgitation. During the past 4 months his murmur has become much more prominent. In addition, he has experienced severe dyspnea with light physical activity and 3+ pitting edema over both lower legs. Physical examination is notable for coarse rales and an S_3 gallop. For the past 6 weeks, he has been maintained on digoxin and diuretics without significant relief of his shortness of breath (SOB). The cardiothoracic surgeon recommends mitral valve replacement and orders the following surgical antibiotic prophylaxis regimen: cefazolin 1 g IV preoperatively, then every 8 hours for 24 hours. Is cefazolin the most appropriate antimicrobial for L.G.? Why was prophylaxis ordered for only 24 hours?

Although the incidence of postoperative wound infection for cardiothoracic procedures is low (<5%), the devastating consequences of a postoperative endocarditis (after valve replacement) and mediastinitis or sternal osteomyelitis (after sternotomy) warrant antimicrobial prophylaxis.[44–46] Common pathogens associated with cardiothoracic surgery include Staphylococcus aureus and Staphylococcus epidermidis (particularly with hardware placement) (Table 63-2); based on these potential pathogens, successful prophylactic regimens include cefazolin and cefuroxime. When cefazolin has been compared with cefuroxime or cefamandole, a statistical trend in favor of the second-generation cephalosporins has been noted, and collective wound infection rates were slightly higher in the cefazolin group.[47–49] In contrast, a comparison of prophylactic cefazolin and cefuroxime in patients having open heart surgery noted a significantly greater incidence of sternal wound infection and mediastinitis in the cefuroxime group.[50] Other studies similarly have not observed improved efficacy with cefuroxime compared with cefazolin.[51],[52] In conclusion, cefazolin probably is at least as effective as second-generation cephalosporins; therefore, the choice of agent should be based on an institution's antimicrobial susceptibility and cost data. Hospital-specific antimicrobial resistance patterns are especially important in determining the incidence of methicillin-resistant S. aureus (MRSA) or methicillin-resistant S. epidermidis (MRSE) surgical site infection rates. Although vancomycin has not been determined to be superior to cefazolin, vancomycin is the drug of choice for prophylaxis in patients colonized with MRSA.[9],[53] Patients are at higher risk of MRSA carriage if they are frequently hospitalized or have a prolonged hospital stay, are exposed to broad-spectrum antibiotics, are known for comorbid conditions, or have severe underlying illness. The population to be screened for MRSA carriage and undergo decolonization with mupirocin is still being debated but is mostly considered for patients undergoing an orthopedic or cardiac procedure. Surveillance of susceptibility of S. aureus isolated from SSIs should be done if mupirocin is used for decolonization.[54]

Meta-analyses reveal no differences between first- and second-generation cephalosporins or between β-lactams and glycopeptides in the prevention of surgical wound infection.[55],[56] Thus, the cefazolin prophylaxis selected for L.G. is acceptable, provided the patient is not colonized with MRSA or MRSE. Additional empiric coverage with an aminoglycoside, a fluoroquinolone, or aztreonam may be considered when gram-negative pathogens are a concern according to local epidemiology and risk factors including hospital admission greater than 48 hours before surgery, diabetes, and ventilator-dependency.[9],[57]

With regard to duration, the shortest effective prophylactic course of antibiotics should be used (i.e., single dose preoperatively or not more than 24 hours postoperatively for most procedures).[58] Postoperative doses after wound closure are usually not required and may increase the risk of resistance. Single-dose prophylaxis, a viable option for many surgical procedures (see Case 63-5, Question 1), is still being evaluated for cardiac procedures.[9] In practice, cardiothoracic antimicrobial prophylaxis often is continued up to 24 hours after surgery, as in L.G. No benefit is seen to prolonging prophylaxis to more than 24 hours, and such use should be discouraged. The duration of antimicrobial prophylaxis ordered for L.G. is appropriate.

CASE 63-5

QUESTION 1: G.J., a 27-year-old woman, is admitted to the obstetrics unit at term with her first pregnancy. She is scheduled for a cesarean section because the baby is in a breech presentation. Cefazolin 1 g IV to be administered after the cord is clamped and every 8 hours for 24 hours is ordered. Is this surgical prophylaxis appropriate or inappropriate?

As noted previously, the shortest effective duration of prophylaxis should be used. In the past, 1- to 5-day antimicrobial regimens were commonly used for cesarean section, but single-dose regimens have been proven to be as effective as these longer regimens.[59] Faro et al.[59] demonstrated that a single 2-g dose of cefazolin was superior to either a single 1-g dose or a three-dose, 1-g prophylactic regimen. Others have noted similar results (i.e., a single cefazolin dose administered after the umbilical cord is clamped is sufficient in preventing postoperative wound infections in cesarean section).[60–63] Single-dose prophylaxis is less costly and minimizes the development of bacterial resistance.[12] Antibiotic prophylaxis has traditionally been administered after clamping of the umbilical cord to minimize infant drug exposure. This early exposure could theoretically mask the signs of neonatal sepsis and favor the acquisition of resistant organisms. However, administration before initial incision and cord clamping decreases the incidence of maternal infections without adverse consequences to the child.[63–65] Thus, G.J. should receive a single 2-g dose of cefazolin before incision, without the three additional doses.

Single-dose prophylaxis has been found to be effective in a variety of GI tract, orthopaedic, and gynecologic procedures.[30] A single dose of an antibiotic with a short half-life, however, may provide insufficient antimicrobial coverage during a prolonged surgical procedure. Repeated intraoperative dosing or selection of an agent with a longer half-life is recommended when the duration of surgery is long to maintain adequate tissue concentrations throughout the procedure.[9],[31]

Signs of Surgical Site Infection

CASE 63-5, QUESTION 2: G.J. is discharged on the fifth hospital day and instructed to observe her incision site carefully for signs of infection. What are the typical signs of site infection? What is the typical time course for signs of site infection to manifest?

Most surgical site infections involve the incision site and are defined as either superficial (involving the skin and subcutaneous fat) or deep incisional (involving fascia and muscle). Typically, an infected incision site wound is red, warm, and purulent and sometimes swollen, tender, or painful. Poor wound healing or dehiscence (premature opening of the incision) is highly suggestive of infection. A surgical site infection can also involve any part of the anatomy (e.g., organs or spaces), other than the incision, which was opened or manipulated during an operation.[16] The purulent drainage, if present, should be cultured to identify the causative pathogen and direct antimicrobial therapy. Empiric therapy directed against the most likely pathogens should be instituted while awaiting culture and sensitivity test results. Although most incision site infections are diagnosed shortly after surgery (within 30 days), some deep-seated infections present indolently during weeks to months, for example, abscess formation.[16] Infection of surgically implanted prosthetic hardware may take place up to a year after the surgical procedure.[16]

Selection of an Antimicrobial Agent

CASE 63-6

QUESTION 1: L.T., a 46-year-old woman, has a recent history of abnormal uterine bleeding and vaginal discharge. Endometrial biopsy is positive for squamous cell carcinoma; however, there does not appear to be an invasive disease. The diagnosis is carcinoma in situ, and a vaginal hysterectomy is scheduled. What would be an appropriate surgical prophylaxis antimicrobial regimen for L.T.?

The selection of a prophylactic regimen should be based on the spectrum of activity of the agents and the most likely pathogens associated with the given surgical procedure (Table 63-2), pharmacokinetic characteristics (e.g., half-life), adverse event profile, impact on bacterial resistance selection, and cost.

The usefulness of antimicrobial prophylaxis in vaginal hysterectomies is well established and should be directed against vaginal microflora, including gram-positive and gram-negative aerobes and anaerobes (Table 63-2).[66] The most-effective, yet most narrow-spectrum agent should be selected considering that the goal of prophylaxis is not to eradicate every potential pathogen but to reduce bacterial counts below a critical level necessary to cause infection. Cefazolin has been proven to be as effective a prophylactic agent as ceftriaxone for vaginal hysterectomy.[67] This finding reinforces the fact that a more broad-spectrum agent (e.g., a third-generation cephalosporin) is unwarranted.

Similar to vaginal hysterectomy, cefazolin and numerous agents (cefotetan, cefoxitin, ampicillin–sulbactam, etc.) decrease the incidence of postoperative surgical infection when the abdominal approach is used.[66],[68] As with vaginal hysterectomy, most trials have not revealed significant differences between first- and second-generation cephalosporins.[68] In contrast, Hemsell et al.[69] observed a significantly higher incidence of major postoperative surgical infections in patients receiving the first-generation agent cefazolin when compared with the second-generation cephalosporin cefotetan. Cefazolin exhibits a favorable toxicity profile and has a relatively long half-life (~1.8 hours), and a single dose has proven prophylactic efficacy.[67] Cefazolin also is considerably less expensive than broader-spectrum agents and is currently recommended by the American College of Obstetricians and Gynecologists.[70] Although it has a broader spectrum of coverage, a single dose of cefoxitin would also be an appropriate choice for this patient.

CASE 63-6, QUESTION 2: Because cefoxitin has an increased spectrum of activity against the anaerobe B. fragilis, it is being considered as an alternative to cefazolin prophylaxis for L.T. Comment on the appropriateness of this proposed change in prophylaxis.

The second- and third-generation cephalosporins and ampicillin–sulbactam generally are not more effective than the first-generation cephalosporins for surgical prophylaxis in vaginal hysterectomy or in gastroduodenal, biliary, and clean surgical procedures.[9] One exception to these findings is in the prevention of infection after colorectal procedures and perhaps hysterectomy. Several investigations have documented the failure of first-generation agents when used as prophylaxis in colorectal procedures, probably a consequence of their weak anaerobic coverage.[71] As stated previously, second- and third-generation agents and ampicillin–sulbactam generally are no more efficacious than cefazolin and should not be used for surgical prophylaxis in most procedures. Cefoxitin, however, would be a reasonable choice in colorectal surgery or hysterectomy. Considering that this patient is having a hysterectomy, either cefazolin or cefoxitin is appropriate.

CASE 63-7

QUESTION 1: S.N., a 57-year-old woman with rheumatoid arthritis and degenerative joint disease, has been admitted for total hip arthroplasty. She states that she had an anaphylactic reaction to penicillin in the past. How does this allergy history impact on the selection of surgical prophylaxis for S.N.?

Cefazolin is the preferred prophylactic agent for most clean procedures, including cardiac, vascular, and orthopedic procedures

(Table 63-2). Although the risk of cefazolin cross-allergenicity to penicillin is relatively low, S.N. experienced a serious, accelerated reaction (hives, SOB) with penicillin; consequently, she should not receive cefazolin. The organisms most likely to cause postoperative infection after total hip replacement are S. aureus and S. epidermidis (Table 63-2). Nafcillin, cefazolin, and vancomycin possess excellent activity against S. aureus; however, the β-lactams have only marginal activity against S. epidermidis. Regardless, nafcillin (and cefazolin) should be avoided because of the penicillin allergy, and the preferred agent for S.N. is vancomycin.

Preoperative vancomycin 15 mg/kg should be administered IV slowly, during at least 60 minutes. This slow rate of infusion is necessary to reduce the risk of infusion-related hypotension.[72]

CASE 63-8

QUESTION 1: B.K., an 18-year-old woman, complains of severe acute abdominal pain and nausea; the pain is localized to the periumbilical region. B.K. has a temperature of 39.5°C. After initial examination by her pediatrician, she is admitted to the hospital with presumed appendicitis, and an exploratory laparotomy is scheduled. What surgical antimicrobial prophylaxis should be ordered for B.K.?

As with colorectal surgery, the most likely infecting organisms in appendectomy are Bacteroides species and gram-negative enterics (Table 63-2). On surgical inspection, if the appendix appears normal (not inflamed, without perforation), then antimicrobial prophylaxis is unnecessary.[73] If the appendix is inflamed without perforation, a single preoperative antibiotic dose is necessary. If the appendix is perforated or gangrenous (complicated), infection is already established and postoperative treatment is warranted. The status of the appendix, however, cannot be determined before surgery; therefore, all patients should receive at least one preoperative dose of an appropriate antibiotic.[74] After surgical inspection of the appendix, the need for postoperative antibiotic therapy can be determined.

Based on the pathogens likely to be encountered, an antimicrobial agent with both aerobic and anaerobic activity should be used. Consequently, cefoxitin is an acceptable choice for prophylaxis.[75]

Risks of Indiscriminate Antimicrobial Use

CASE 63-8, QUESTION 2: On surgical exploration, B.K. was found to have uncomplicated (non-perforated, non-gangrenous) appendicitis; however, cefoxitin therapy was continued for 3 days. What are the risks of indiscriminate use of antimicrobials for surgical prophylaxis?

The risks of indiscriminate use of antimicrobials include the potential for adverse effects and superinfection. The administration of any β-lactam agent poses the risk of a hypersensitivity reaction, and many antibiotics, including cefoxitin, as is being used in B.K., predispose patients to Clostridium difficile–associated disease. The risk of developing this superinfection increases with duration of antibiotic exposure.[11] Avoiding unnecessary initial and prolonged exposure reduces the risk of this superinfection and its associated complications.[76] In addition, prolonged use of antimicrobials increases the selection of resistant organisms in a given patient that could be nosocomially spread to other hospitalized patients.[77]

OPTIMIZING SURGICAL ANTIMICROBIAL PROPHYLAXIS

CASE 63-9

QUESTION 1: As the new infectious disease pharmacist of the institution, you are informed by the infection control team that antibiotic prophylaxis prescribed by the surgeons is not the same as what is indicated in the institution guidelines. Which criteria would you want to measure antibiotic prophylaxis prescription performance? What interventions could improve how antibiotics are used in prophylaxis?

Antibiotic control strategies have improved the appropriate use of antimicrobial agents for surgical prophylaxis. Numerous factors including individual knowledge, attitudes, beliefs, and practice; team communication and allocation of responsibilities; and institutional support for promoting and monitoring practice influence antibiotic prophylaxis measures.[78] Interventions for improvement are focused on education of practitioners, standardization of the ordering, the delivery and the administration processes, and providing feedback on performance as measured by infection rates and compliance with improvements. The Surgical Care Improvement Project (SCIP), a national multidisciplinary initiative developed by the Centers for Medicare and Medicaid Services, aims at improving surgical care. Reducing surgical site infections is among one of the targeted goals of this initiative.[79] Prophylactic antimicrobial received within 1 hour before surgical incision, prophylactic antimicrobial consistent with published guidelines, and prophylactic antimicrobial discontinued within 24 hours of surgery end time are three performance measures included in this quality improvement process. The first two, antibiotic timing of administration and appropriate antibiotic selection, are associated with a decrease in the surgical site infection rate.[8]

Smaller scale projects have also been successful at improving antibiotic use and decreasing infection rates. A multidisciplinary team generated electronic quick orders allowing for a computer-enhanced decision-making process and developed an antibiotic administration protocol. Appropriate selection of antibiotics increased from 78% to 94%, timely administration improved from 51% to 98%, and clean wound infection rate decreased from 2.7% to 1.4%.[80]

In collaboration with other health care providers, pharmacists should be responsible for optimizing the timing, choice, and duration of antimicrobial surgical prophylaxis. Education of surgical, anesthesia, and nursing staff, supported by hospital policy changes initiated by pharmacists, improved appropriate timing from 68% to 97% and resulted in significant cost avoidance.[81] Post-discharge surveillance is also critical in reducing surgical site infections.[82]

Vaccinations

Molly G. Minze and Katherine Dillinger Ellis

CORE PRINCIPLES	CHAPTER CASES
GENERAL VACCINE PRINCIPLES	
1 **Adverse Effects:** Immunization adverse effects are in part dependent upon the type of vaccine preparation used. Adverse effects from live attenuated vaccines mimic the disease but are less severe and occur 7 to 10 days postvaccination. Inactivated (killed whole virus) vaccination adverse effects include soreness at the site of administration within 24 hours after vaccination. Vaccination adverse effects are significantly less severe than the disease itself.	**Case 64-1 (Question 1)**
2 **Immunization Schedules:** Recommended immunization schedules are designed to optimize immune response, standardize regimens, and enhance immunization rates. Birth to 18 years and adult immunization schedules are reviewed and updated annually.	**Case 64-2 (Question 1)**
3 **Catch-up Immunization Schedules:** To catch up within an immunization series, it is not necessary to restart from the first dose of the schedule. A delay in receiving subsequent doses does not interfere with final immunity gained from the vaccination.	**Case 64-3 (Question 1)**
INACTIVATED VACCINES	
1 **Hepatitis B:** Hepatitis B vaccination is effective for both pre-exposure and postexposure prophylaxis. To prevent vertical transmission to an infant from a mother, it is key to provide vaccination within 12 hours of birth along with hepatitis B immunoglobulin for those mothers who test hepatitis-B–positive.	**Case 64-4 (Question 1)**
2 **Hepatitis B:** The highest incidence of hepatitis B infection occurs in young adults. Hepatitis B vaccination is recommended for adults who participate in high-risk behaviors and those in close contact with the infected persons.	**Case 64-4 (Question 2)**
3 **Hepatitis A:** Hepatitis A immunization is targeted toward toddlers with the aim of preventing transmission to adolescents and adults.	**Case 64-5 (Question 1)**
4 **Diphtheria, tetanus, and acellular pertussis/Pertussis booster:** Waning immunity against pertussis has resulted in outbreaks of pertussis	**Case 64-6 (Question 1)**

	in the United States. Adolescents and adults, particularly those with close contact with young infants, should receive a single dose of pertussis booster vaccine.	
5	**Haemophilus influenzae b:** Immunization recommendations for Haemophilus influenzae type b is age-dependent. The older an infant is at presentation, the fewer doses needed to elicit a response. A single vaccine dose may be considered in children and adults with underlying diseases that place them a risk for infection.	**Case 64-7 (Question 1)**
6	**Polio:** Inactivated polio vaccine is recommended over the oral attenuated vaccine for polio vaccination in the United States because inactivated vaccine is associated with a lower incidence of vaccine-associated paralytic polio.	**Case 64-8 (Question 1)**
7	**Polio:** Routine vaccination of adults against polio with inactivated poliovirus vaccine is not recommended unless individuals plan travel to endemic areas. Oral polio vaccine may be considered only in unique situations.	**Case 64-9 (Question 1)**

8	**Meningococcal:** Vaccination is recommended within populations at increased for risk for contracting Neisseria meningitidis, including travelers to endemic areas, patients with specific immunodeficiencies, functional/anatomic asplenia, lab personnel dealing with meningococcus, and college students.	**Case 64-10 (Question 1)**
9	**Human Papillomavirus:** This three-dose vaccination series is recommended for adolescent females for the prevention of cervical and anogenital cancers, anogenital warts, and recurrent respiratory papillomatosis. It is also recommended for males in the prevention of genital warts.	**Case 64-11 (Question 1)**
10	**Pneumococcus:** Streptococcus pneumoniae mostly affects young children and the elderly. The conjugate vaccines protect against 80% (PCV 7) and 90% (PCV 13) of infectious strains that cause disease in children younger than 6 years old.	**Case 64-12 (Question 1)**
11	**Pneumococcus:** The polysaccharide vaccine does not elicit immune response in children younger than 2 years old, and protects against 23 strains of S. pneumoniae that typically cause adult disease.	**Case 64-12 (Question 2)**
12	**Influenza:** Vaccination is recommended for anyone older than 6 months of age who does not have a current contraindication. The inactivated vaccine is delivered intramuscularly or intradermally, whereas the live attenuated vaccine is delivered as a nasal spray formulation.	**Case 64-13 (Question 1)**

LIVE ATTENUATED VACCINES

1	**Rotavirus:** Infants vaccinated with the rotavirus vaccine shed the virus in the feces after immunization; however, the risk of transmission to an	**Case 64-14 (Question 1)**

immunocompromised contact is relatively low with appropriate precautions.	
2 **Measles/Mumps/Rubella (MMR):** Parents are fearful of the risk of autism which has been falsely associated with the MMR vaccine. Pharmacists must provide counseling to overcome parental fears and ensure protection against measles.	**Case 64-15 (Question 1)**
3 **Varicella:** Postexposure vaccination with the varicella vaccine is recommended within 5 days of exposure for those unvaccinated or who have not received a second dose of vaccine.	**Case 64-16 (Question 1)**
4 **Varicella:** Herpes zoster vaccination is recommended in adults older than 60 years of age to prevent reactivation of previously acquired wild-type varicella zoster infections. It is not recommended for anyone who previously received the varicella zoster vaccine.	**Case 64-16 (Question 2)**
IMMUNIZATION PRACTICES	
1 **Vaccine Administration:** Intramuscular vaccinations are administered at a 90-degree angle into the muscle using a 1-inch needle. Subcutaneous vaccinations are administered at a 45-degree angle into the subcutaneous tissue by pinching this tissue up to prevent insertion into the muscle. When multiple injections are given at the same site, separate each injection by 1 inch.	**Case 64-17 (Question 1)**
2 **Advocacy and Establishing Services:** Pharmacists have an important role as immunization advocates to positively increase immunization rates. Pharmacist immunization training is widespread throughout the United States, but pharmacists must adhere to guidelines and principles established by their state pharmacy practice act when administering immunizations to patients.	**Case 64-18 (Question 1)**

The use of immunizations to control common infectious diseases is a major public health achievement. Children, adolescents, and adults are now routinely immunized against 17 infectious diseases.[1] Immunization rates are high overall and have remained stable in the United States with more than 80% of children 3 years of age receiving all the recommended vaccines.[2] As a result, low levels of vaccine-preventable diseases are occurring. Rates of immunization for adults against influenza and pneumococcus range from 20-43%, with higher coverage for individuals older than 65 years.[3] Unfortunately, despite overall high rates of immunization coverage, disparities still exist in vaccination coverage for the socioeconomically disadvantaged and by ethnicity.[2] Clearly, there is room for improvement and an opportunity for all health professionals to have an impact.

The need for timely immunization administration is key to preventing disease resurgences.[4] As the incidence of vaccine-preventable disease continues to decrease, patients are becoming less aware of the significance and severity of the diseases that could be prevented.[5–8] This, along with parental concerns regarding vaccine safety, may jeopardize previous vaccination achievements.[7] Health care providers play a vital role in clarifying misconceptions and educating parents and other health professionals about the importance of proper and complete immunizations.[7] Any contact with a patient represents an opportunity to promote immunization, and thus every medication history should include a review of immunization status to detect any deficiencies.[8]

VACCINE PRINCIPLES

General Principles

The principle of vaccination against disease is that the introduction of a small amount of the pathogen to the body produces protective immunologic memory (active immunity) and, if the pathogen is reintroduced at a later date, a greater immunologic response is elicited but without inducing disease.[9] The ideal vaccine would present a non-virulent form of a pathogen that produces a strong immunologic response once in the body.[10]

Current vaccine types include live attenuated, killed (inactivated) whole organism, subcellular/subunit, and DNA-based vaccines.[10] (See Table 64-1 for a listing of common vaccines and their formulation type.) Live attenuated vaccines contain weakened or inactivated forms of the pathogen, which causes replication within the host and ultimately elicits antibody and cell-mediated immunity within the body via B-cell and T-cell responses.[10],[11] Live vaccine administration produces a mild, typically asymptomatic infection at the time of vaccination followed by long-lived immunity from a single immunization.[12],[13]

Killed whole organism and subcellular/subunit vaccines do not replicate within the host, nor can they revert to pathogenicity, but they often require adjuvants and/or multiple doses to increase the duration of immune response to the antigen.[9],[10] Because the organisms in whole pathogen vaccines are inactivated (killed), their effectiveness may be impaired by circulating antibodies, maternal antibodies (in infants), or concomitant infections. Toxoids are a specific kind of inactivated vaccine formed by modifying a biological toxin (e.g., diphtheria and tetanus), usually by mixing it with formaldehyde.

Subunit vaccines contain either a protein or polysaccharide antigen within the vaccine and elicit less reaction than whole pathogen vaccines, thus immune responses are weaker and require multiple doses similar to inactivated vaccines.[9] Conjugated subunit vaccines, consisting of a polysaccharide-protein-conjugate where the protein is the antigenic toxin, produce improved immune responses because of B-cell activation by the polysaccharide component and T-cell activation by protein component. Recombinant vaccines available include hepatitis B, human papillomavirus (HPV), recombinant influenza, and live typhoid vaccine.[14]

Adverse Effects

CASE 64-1

QUESTION 1: H.P. is a 38-year-old woman concerned about the side effects of the annual influenza "shot." What information can be provided regarding expected adverse effects for H.P.?

Adverse reactions to inactivated vaccines include pain at the injection site and fever within 48 to 72 hours of administration.[15–17] In contrast, adverse effects from live attenuated vaccines occur 7 to 10 days after immunization, after the virus has replicated and the immune system has responded. Adverse reactions to live attenuated vaccines mimic the symptoms of disease. Transient rash occurs in 5% of patients receiving measles, mumps, rubella (MMR) immunizations, and a mild varicella-like rash (median of five lesions) occurs in fewer than 5% of patients receiving the varicella vaccine. Syncope, usually occurring within 30 minutes of immunization, has been reported, with 70% of syncopal episodes occurring within 15 minutes of immunization, and occurs more commonly in female patients and adolescents.

Although anaphylactic reactions to vaccines are rare, an allergic reaction may occur as a result of specific allergy to the vaccine itself or to trace components in the vaccine (e.g., preservatives, antibiotics).[18] Patients with egg allergy can receive vaccines produced in chick-embryo-fibroblast tissue culture (e.g., MMR) because the risk for serious reaction to these vaccines in egg-allergic individuals is very low.[19–21] MMR should be used cautiously in individuals with a history of a severe reaction to gelatin, which is a stabilizer in the MMR vaccine. Trace amounts of streptomycin, bacitracin, and neomycin are present in oral polio virus vaccine, inactivated polio vaccine, and MMR; therefore, these vaccines should not be administered to individuals with a history of an anaphylactic reaction to these antibiotics.[22]

Overall, vaccinations are safe, especially when compared with the risks of the diseases that these vaccines prevent, and the safety of immunizations are scrutinized continually.[22–24] In response to concerns about vaccine safety, the National Vaccine Injury Compensation Act mandated an ongoing review of evidence regarding the possible adverse effects of vaccines and established a no-fault injury compensation program for selected vaccines.

Contraindications

Misconceptions about contraindications and precautions for immunization often result in missed opportunities to provide needed immunizations.[1,25] Acute, severe febrile illness; history of anaphylaxis to the vaccine or vaccine components; and history of a severe reaction to an immunization are clear contraindications to immunizations. Immunizations, however, should not be delayed in a patient who has a minor illness (e.g., upper respiratory tract infection, otitis media, diarrhea) even in the presence of a low-grade fever. A family history of seizures, allergies, and sudden infant death syndrome are not contraindications for immunizations. Immunization of a patient with a history of anaphylaxis to a vaccine or vaccine component should be withheld until he or she has undergone desensitization. Preterm infants should begin to receive routine immunizations based on their chronological age for all vaccines, although initiation of the hepatitis B series should begin at 1 month of age.

Allergic reaction to previous exposure to vaccine components, immunosuppression (e.g., immunosuppressive therapy, immunodeficiencies), encephalopathy, recent administration of blood products, and pregnancy (although the risk in pregnancy is largely theoretical) are contraindications to live attenuated virus or live bacterial vaccines. Pooled blood products (e.g., immunoglobulins, packed red blood cells, platelet transfusions) can impair the immune response to a live vaccine because these products contain antibodies, which can prevent one's immune system from mounting an adequate response.[1] The impairment of an immune response to an immunization varies, depending on the type and amount of blood product administered, and immunizations may need to be delayed for up to 12 months if pooled blood products have been administered recently.[1] With any question about immune response, antibody titers can be obtained to determine if a patient needs to be re-immunized.

Table 64-1

Vaccine Overview

	Vaccines	Recommended Regimens	Comment
Diphtheria, tetanus, pertussis (inactivated; intramuscular)	DTaP, DT Tdap Td	2, 4, 6, 15–18 months; booster at 4–6 years 11–12 years Every 10 years	Minimum age 6 weeks; fourth dose can be administered at 12 months of age if at least 6 months since third dose Minimum age 10 years (Boostrix) and 11 years (Adacel)
Haemophilus influenzae type b (inactivated; intramuscular)	Hib	2, 4, 6, 12–15 months	Minimum age is 6 weeks If PRP-OMP at 2 and 4 months, no 6-month dose indicated

			Hiberix should only be used for final dose (12 months–4 years)
Hepatitis B (inactivated; intramuscular)	Hep B	Birth, 1–2 months, 6–15 months	Monovalent vaccine to be administered for any doses before 6 weeks Administer birth dose within 12 hours if HBsAG+ mother Final dose should not be given before 6 months of age
Hepatitis A (inactivated; intramuscular)	HepA	Two doses 6 months apart First dose at 23 months	Minimum age 12 months
Human papillomavirus vaccine (inactivated; intramuscular)	HPV2 HPV9	Three doses 9–26 years Second dose 1–2 months after first Third dose 6 months after first	Administer to females before sexual activity Administer to males to reduce likelihood of genital warts
Influenza (IIV = inactivated; intramuscular) (LAIV 4 = live attenuated; intra-nasal)	IIV, LAIV4	Annually Two doses 4 weeks apart at first annual vaccination	Minimum age IIV 6 months Minimum age LAIV 4 2 years Two doses required for patients aged 2–8 years at first annual vaccination
Measles, mumps, rubella (live attenuated; subcutaneous)	MMR	12–15 months; repeat dose 4–6 years	Minimum age 12 months; second dose may be administered at 4 years as long as 4 weeks from previous dose
Meningococcal (MCV = inactivated; intramuscular) (MPSV = subcutaneous)	MCV4 MPSV4	Two doses 8 weeks apart age 2–10 years One dose age 11–55 years Ages 56 and older	Minimum age 2 years Two doses for patients with immunodeficiency One dose for patients at high risk
Pneumococcal (inactivated polysaccharide; usually intramuscular, but subcutaneous ok)	PCV 13 PPSV 23	2, 4, 6, 12–15 months 1 PCV 13 dose 1 dose ≥65 years 2 doses if <65 at time of first dose	PCV minimum age 6 weeks PPSV minimum age 2 years Administer PCV 13 dose before PPSV 23 Administer second dose of PPSV 5 years after first
Polio (inactivated; usually intramuscular, but subcutaneous ok)	IPV	2, 4, 6–18 months	IPV minimum age 6 weeks If four or more doses given before 4 years of age, repeat booster at 4–6 years Final dose should be after fourth birthday and at least 6 months after previous dose
Rotavirus (live attenuated; oral)	RV1 RV5	2, 4 months 2, 4, 6 months	Initial dose: minimum age 6 weeks, maximum age 14 weeks 6 days Final dose: maximum age 8 months Rotarix (RV1): 6-month dose not indicated
Varicella (live attenuated; subcutaneous)	VZV	12–15 months; repeat dose at 4–6 years	Minimum age 12 months; second dose may be administered at 4 years as long

			as 3 months from previous dose
Zoster (live attenuated; subcutaneous)	ZV	50 years of age (usually >60)	1 dose

HBsAG+, hepatitis-B–surface antigen positive; PRP-OMP, PedvaxHIB or Comvax (Hep B-Hib).

GUIDELINES

Schedule for Immunizations

CASE 64-2

QUESTION 1: K.C., a 2-month-old baby girl, is brought to the clinic for a scheduled well-baby visit. K.C.'s mother inquires about immunizations for her daughter. What are the current recommendations for immunizing pediatric patients? When should these immunizations be given to K.C.?

The goal of immunization is to prevent specific infectious diseases and their sequelae. For maximal effectiveness, a vaccine must be administered to the susceptible population before anyone has been exposed to the pathogen. The age at which immunizations are administered to specific individuals depends on several factors (e.g., age-specific risks of the disease, risks of complications, presence of maternal antibodies transferred through the placenta, maturity of the immune system). Usually, immunizations are administered at the youngest age that the child is able to develop an adequate antibody response.

The recommended childhood and adolescent immunization schedules are reviewed annually by the Advisory Committee on Immunization Practice (ACIP) and American Academy of Pediatrics (AAP), and supported by the American Academy of Family Physicians (AAFP), the American College of Obstetricians and Gynecologists (ACOG), and published within the Morbidity and Mortality Weekly Report[26],[27] and are available online (http://www.cdc.gov/schedules). A partial summary of vaccination schedules is included in Table 64-1, but the reader is referred to the online publication of immunization schedules for a more complete listing of the most current recommendations. The minimal immunization requirements for entry into public schools and day-care centers vary with each state and the departments of health of individual states need to be consulted for these guidelines. The ACIP reviews the adult immunization schedule annually as supported by the American College of Physicians (ACP), American Academy of Family Physicians (AAFP), and the American College of Nurse-Midwives (ACNM) and published within the Annals of Internal Medicine and Morbidity and Mortality Weekly Report[28–30] (available online at http://www.cdc.gov/schedules). The respective schedules for children and adults should be reviewed annually, and policies and procedures revised to ensure compliance.

A review of the childhood immunization schedule reveals that the recommended vaccines to be administered at 2 months of age include diphtheria, tetanus, and acellular pertussis (DTaP), inactivated polio (IPV), Haemophilus influenzae type b (Hib), conjugated pneumococcal vaccine (PCV13), and rotavirus vaccine. A second dose of the Hepatitis B (Hep B) vaccine should also be administered if the first dose was given at birth. If Hep B vaccine was not given to K.C. at birth, the first dose should be given today, then repeated at 1 to 2 months and again at 6 months (see Case 64-4 Question 1).

CASE 64-3

QUESTION 1: K.C.'s mother also mentions that she personally received two doses of an HPV vaccine series. Her physician asked her to receive a third dose in December, and it is now March. Does K.C.'s mother need to restart the vaccination series for HPV?

Immunization schedules can be adjusted to meet individual needs and may begin at any time of the year. Vaccines should not be administered at time intervals shorter than those recommended to allow for maximal immune responses before the administration of subsequent doses.[1] A "catch-up" schedule for immunizations of children and adolescents who begin their immunizations late or who are more than 1 month behind schedule in their immunizations and recommendations for minimal intervals between doses for the administration of various vaccine can be implemented.[1,26,27] It is not necessary for adults who delay administration of a subsequent dose of an immunization series to restart the vaccination series. An interruption or delay in the recommended schedule does not interfere with the final immunity gained.

Alternative immunization recommendations are available for patients with altered immunocompetence to ensure protection from vaccine associated disease, yet prevent adverse effects or acquiring disease from the vaccine itself in the case of live attenuated vaccines.[1,27,30,31] K.C.'s mother should receive a third dose of HPV vaccine as soon as possible, but she does not need to restart the whole series.

INACTIVATED VACCINES

Hepatitis B

CASE 64-4

QUESTION 1: A.G. is an infant (weight 2,100 g) born to a mother in whom the hepatitis B surface antigen (HBsAg) status is unknown. How should A.G. be managed?

Hepatitis B virus (HBV) can be transmitted via exposure to contaminated blood (e.g., blood products or medical instruments, non-sterilized needles used in intravenous drug abuse, or tattooing), exposure to body fluids (e.g., sexual intercourse), and transplacentally from an HBsAg-positive mother. The prevention of HBV maternal transmission to an infant is essential because acute disease can progress to a chronic carrier state, which can lead to chronic liver disease and primary hepatocellular carcinoma. Children acquiring HBV infection before 5 years of age are at an especially high risk of developing chronic infection.[32] All pregnant women should be tested for HBsAg, and infants born to HBsAg-positive mothers should receive their first vaccine dose in addition to hepatitis B immune globulin (HBIG) within 12 hours of birth to prevent vertical transmission.[33] When combined, HBIG plus HBV vaccine are 99% effective in preventing acute and chronic infection in infants born to HBsAg-positive mothers.[33] If the mother's HBsAg status is unknown, the infant should be also immunized within 12 hours of birth regardless of birth weight. For infants weighing less than 2,000 g, HBIG should also be administered within 12 hours of birth. The mother's HBsAg status should be determined as soon as possible and if the mother is HBsAg-positive, HBIG should be administered to infants weighing >2,000 g as soon as possible, but no later than day 7 of life.[33] Infants weighing >2,000 g born to HBsAg-negative mothers should begin their immunization series within 24 hours of birth. All other infants born to HBsAg-negative mothers should begin their immunization series before hospital discharge. In all situations, subsequent vaccine doses should be administered at age 1 to 2 months and again at age 6 months. All unimmunized children should receive HBV vaccine as soon as they are identified.[33]

AG should receive Hep B vaccine within 12 hours of birth and the mother's status should be determined. If her mother is found to be HBsAg-positive, HBIG should also be administered within 7 days of birth. A.G. can receive her subsequent doses of HBV vaccine according to the childhood immunization schedule. Two Hep B vaccines are currently available for use in the United States. Recombivax-HB and Engerix-B are yeast-derived recombinant vaccines administered as a three-dose series.[33],[34] Either formulation

---

can be used because the immune response from an immunization series using different vaccines is comparable to that of a full series using a single vaccine.[1],[35]

CASE 64-4, QUESTION 2: A.G.'s mother has not been immunized herself against hepatitis B. Should she begin receiving the Hep B series as well?

Despite a decline in hepatitis B infections in the United States after universal childhood immunization, more than a million adults are living with chronic hepatitis B infection. The highest incidence of acute hepatitis B in the United States occurs in adults 25 to 45 years of age, the majority of which occur in individuals with high-risk behaviors including multiple sexual partners, anal intercourse, and injectable drug abuse.[34] Individuals who have close contact with patients infected with hepatitis B, including health care workers, are also at risk of infection.[34] Children and adolescents not vaccinated during infancy should be given a three-dose series of intramuscular injections. Similarly, adults aged 19 to 59 years old with type 2 diabetes are recommended to receive the three-dose series.[36] Other at-risk adult groups who should receive the hepatitis B vaccination include sexually active persons not in a long-term monogamous relationship, persons seeking treatment for a sexually transmitted infection, or men who have sex with men, patients with end-stage renal disease, HIV, who receive hemodialysis or have chronic liver disease, household contacts and sexual partners of hepatitis B surface antigen positive persons, staff of institutions for persons with developmental disabilities, international travelers to areas with high prevalence of hepatitis B, and adults in settings of STD treatment facilities, HIV testing and treatment facilities, or facilities providing care for patients at risk of having hepatitis B.[28–30,34] Antibody screening after immunization is only recommended in high-risk groups in whom future clinical management may depend on knowledge of immune status (e.g., health care workers). Recommendations for serologic testing and revaccination and postexposure prophylaxis for such situations are available.[34] Patients on dialysis and other immunocompromised patients may require a fourth dose if the anti-HBs level is less than 10 MIU/mL 2 months after the third dose.[34]

A.G.'s mother should begin a three-dose series of Hep B vaccine. Monovalent vaccines are preferred for the initial vaccination; however, combination vaccines may be used[1],[35] (see Table 64-2). Combination vaccines should not be used for infants younger than 6 weeks of age; therefore, only single antigen doses should be used for birth doses.[33]

Hepatitis A

CASE 64-5

QUESTION 1: A mother presents with her 2-year-old to her pediatrician for a well-child visit. Her pediatrician encourages her to have her child immunized against hepatitis A. What are the differences between hepatitis B and hepatitis A infections, and what are the immunization recommendations?

Hepatitis A infection can present as either an acute or chronic illness, but it is often asymptomatic in infants and young children. However, infections in older children and adults typically present with fever, malaise, anorexia, nausea, abdominal discomfort, and jaundice.[37] Clinical illness usually lasts 1 to 2 months, but it may be relapsing and can last up to 6 months. Approximately one-third of hepatitis A cases occur in children younger than 15 years of age.[38] Among all reported cases, the most common source of infection is household or sexual contact, followed by day-care attendance or employment, international travel, and food or waterborne outbreaks. Asymptomatic children serve as a source of infection, especially for household or other close contacts.[38]

Vaccination programs targeting toddlers and young children are important because children are often asymptomatic and unwittingly transmit the virus to adolescents and adults. In addition, data suggest a "herd effect" when vaccination of children is widespread (i.e., large population immunization programs indirectly protect those who are not immunized because the risk of being exposed to an infected individual is reduced).[39] A program aimed exclusively at toddlers in an endemic area reduced the prevalence of hepatitis A by more than 90%, not only in the 2- to 4-year-old vaccine recipients but in all age groups.[39]

Table 64-2

Combination Vaccines

Combination Vaccine[a]	Antigens[b]	Age Indicated	Regimen
Kinrix	DTaP-IPV	4–6 years	Only for fourth dose IPV and fifth dose DTaP
Quadracel	DTap-IPV	4-6 years	For fourth or fifth dose IPV series and fifth dose DTaP
Pediarix[c]	DTaP-Hep B-IPV	6 weeks–6 years	2, 4, 6 months
Pentacel	DTaP-IPV-Hib	6 weeks–4 years	2, 4, 6, 15–18 months An extra monovalent IPV recommended for IPV at 4–6 years (total, five doses)
ProQuad[d]	MMR-V	12 months–12 years	12–15 months, 4–6 years
Twinrix	HepA-Hep B	18 years+	0, 1, 6 months

[a] Vaccine interchangeability: If combination and single antigen vaccines are used to complete an immunization series, it is preferred to use products from the same manufacturer. Immunogenicity of vaccine antigens between different manufacturers is unknown.

[b] Extra antigens: Administration of extra antigens by using combination vaccines should be avoided. Availability of monovalent vaccines should be provided to avoid giving extra antigens and increase risk of adverse effects, particularly for inactivated vaccines which are reactogenic (e.g., DTaP vaccine).

[c] Hepatitis B: Combination vaccines not recommended for hepatitis B birth doses (<6 weeks).

[d] ProQuad: MMRV may be associated with an increased risk of febrile seizures when used at age 12–47 months. The use of MMR is preferred during this time.

DTaP, diphtheria, tetanus, and acellular pertussis; HepA, hepatitis A; Hep B, hepatitis B; Hib, Haemophilus influenzae type b; IPV, inactivated poliovirus vaccine; MMR, measles, mumps, and rubella vaccine; V, varicella vaccine.

Sources: National Center for Immunization and Respiratory Diseases. General recommendations on immunizations—recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR Recomm Rep. 2011;60:1; CDC. Combination vaccines for childhood immunization: recommendations of the Advisory Committee on Immunization Practices (ACIP), the American Academy of Pediatrics (AAP), and the American Academy of Family Practice (AAFP). Pediatrics. 1999;103:1064; Marin M et al. Use of combination measles, mumps, rubella and varicella vaccine: recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR Recomm Rep. 2010;59(RR-3):1.

There are two hepatitis A (Hep A) vaccines on the market, Havrix and Vaqta, each with adult and pediatric formulations. The pediatric formulations of the vaccine are indicated for infants older than 12 months of age and contain half the antigen of the adult formulations.[37] Vaccination involves a two-dose regimen with the second dose to be administered 6 to 18 months after the initial dose, depending on the formulation (see Table 64-1). Two doses of hepatitis A vaccine should be administered at least 6 months apart to previously unvaccinated persons who live in areas where vaccination programs target older children, or who are at increased risk for infection.[27] Adults for whom Hep A vaccination is recommended include those with high-risk behaviors, individuals who work with hepatitis A virus-infected primates or in a hepatitis A research laboratory setting, patients with chronic liver disease or who require clotting factor concentrates, and those traveling to areas where hepatitis A is endemic.[28–30,37] A combination vaccine containing both Hep A and Hep B is available and indicated in individuals older than 18 years of age on a three-dose schedule (see Table 64-2).

Diphtheria/Tetanus/Pertussis Vaccines

CASE 64-6

QUESTION 1: N.R. is a nurse who cares for children in a hospital setting. She calls with confusion regarding the need for her to receive a "pertussis booster." She indicates that she received her DTaP immunization series as recommended during childhood and her last tetanus shot was 3 years ago. Should N.R. receive the pertussis booster (Tdap)?

Pertussis ("whooping cough"), an infectious disease caused by Bordetella pertussis, is characterized by a paroxysmal cough with a whoop-like, high-pitched inspiratory noise; vomiting; and lymphocytosis. It is a highly communicable infection, which can affect 90% of infants and young children in nonimmunized households, and can be associated with serious sequelae, particularly in young infants. An estimated 0.3% to 14% of patients with pertussis experience encephalopathy, 0.6% to 2% have permanent neurologic damage, and about 0.1% to 4% die.[40] This serious childhood infection has been mitigated with the availability of an acellular pertussis vaccine (aP), which commonly is administered in combination with diphtheria (D) and tetanus (T) vaccines (DTaP). A primary series of four doses of DTaP is recommended at 2, 4, 6, and 15 to 18 months followed by a booster dose at school entry or 4 to 6 years of age.[27],[41] The efficacy of the DTaP vaccines against pertussis after primary immunization (three doses) is greater than 80%.[41] Protection increases to 90% after the last booster (age 4–6 years) and then decreases during the next 12 years, after which protection is minimal.[42],[43]

Historically, DTaP vaccines contained whole cell pertussis antigens. However, because of concerns regarding adverse effects, products currently available contain acellular pertussis antigens (see Table 64-1). Despite a more favorable adverse effect profile, the DTaP vaccine is contraindicated in anyone experiencing an anaphylactic reaction or encephalopathy within 7 days of immunization with DTaP when these symptoms cannot be attributed to another cause.[41] In addition, careful consideration of subsequent doses should be given to infants experiencing a temperature of 105°F (not resulting from another cause) or persistent, inconsolable crying lasting more than 3 hours within 48 hours after the administration of a pertussis-containing vaccine.[41] The pertussis component of the DTaP vaccine should be eliminated (i.e., continue vaccination with DT) in any child experiencing collapse or a hypotonic–hyporesponsive episode. If an evolving neurologic disorder is present, pertussis immunization should be deferred until the neurologic problem has been fully evaluated. Preexisting, stable neurologic conditions (e.g., well-controlled seizures) are not contraindications because the benefits of pertussis immunization outweigh the risks. A family history of seizures or other central nervous system (CNS) disorder is not a contraindication for vaccination.[42]

Two DTaP vaccines (Infanrix and Daptacel) are approved for the primary vaccination series. Combination vaccines may also be used; however, their use for primary vaccination is product dependent (Table 64-2).[35] If possible, the same DTaP product should be used for all five doses because the immunity, safety, and efficacy associated with the interchanging of different DTaP vaccines are unknown.[1],[27] If the product information is unknown or unavailable from prior vaccinations, however, any licensed DTaP vaccine can be used to complete the vaccination series.[1],[27]

Despite the availability of an effective vaccine and a high rate of vaccine coverage, pertussis remains poorly controlled in the United States.[44] Decreased immunity in adolescents and adults is believed to contribute to this problem. About 12% of adult patients with a cough lasting more than 2 weeks have pertussis.[45] Although the illness is typically mild in adults and adolescents, they serve as a source of transmission to unprotected infants. This has led to the development and recommendation of acellular pertussis booster vaccines for adolescents and adults with a tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap).[1],[27],[44] (Note the designation as dap compared with DaP for primary vaccines.) The routine use of a single dose of pertussis booster (Tdap) is recommended for adolescents at 11 to 18 years of age, for adults 19 to 64 years of age, pregnant females during each pregnancy, and for those older than 65 years of age who may be in contact with infants younger than 12 months of age.[27–30,44,46] The pertussis booster (Tdap) may be administered regardless of the time since receipt of a tetanus booster (Td). Two Tdap vaccine formulations (BOOSTRIX and ADACEL) are US Food and Drug Administration (FDA)–approved for use as a booster dose for children 11 to 18 years of age.[44] Recommendations for catch-up immunization of unvaccinated or undervaccinated individuals with DTaP/Tdap are available.[1],[27–30] N.R. should receive the Tdap vaccination, particularly because she works in an environment with young children, and she has not received a booster since her childhood DTaP series. She may be given a dose without regard to her prior tetanus booster vaccination.

Diphtheria and tetanus toxoids have been administered in combination with pertussis vaccination in the United States since the 1940s. Both diphtheria and tetanus are rare diseases in the United States as a result of universal childhood immunization. When disease does occur, it does so primarily in the elderly or those who were inadequately vaccinated.[47] For both diseases, it is the toxin-producing strains (toxigenic Corynebacterium diphtheriae and Clostridium tetani) that result in severe disease and, therefore, the vaccine antigens target the toxoids which they produce. The concentration of diphtheria toxoid in vaccine preparations for adults (designated as d as compared with D in primary vaccination) is reduced relative to those for children owing to increased reactions with repeated injections and improved response to lower antigen doses.[47] DTaP and diphtheria and tetanus toxoids (DT) are to be used for primary vaccination in children younger than 7 years of age, whereas the tetanus and diphtheria toxoids (Td) are for use in children older than 7 years of age and adults. Booster doses of tetanus (Td) should be administered every 10 years.[47]

Haemophilus Influenzae B

Haemophilus influenzae type b (Hib) was the most common cause of bacterial meningitis and a leading cause of serious, systemic

---

bacterial diseases in children younger than 5 years of age until an effective vaccine was added to the routine immunization schedule.[48–50] The mortality rate associated with Hib meningitis was approximately 5%, with neurologic sequelae observed in 25% to 35% of survivors.[51],[52] Epiglottitis, cellulitis, septic arthritis, osteomyelitis, pericarditis, and pneumonia also were commonly caused by H. influenzae. Although

H. influenzae is associated with otitis media and respiratory tract infections, type b strains account for only 5% to 10% of these infections.[53],[54]

CASE 64-7

QUESTION 1: P.M. is a 12-month-old child who has not been immunized against Hib. His parents wish to enroll him in day care and are now trying to catch him up on his immunizations. How many doses of vaccine against Hib should he receive?

The Hib vaccine is a conjugate polysaccharide vaccine which is associated with a 95% reduction in the incidence of Hib disease in children younger than 5 years of age.[54] The three currently available monovalent conjugate Hib vaccines are as follows: Hib meningococcal protein conjugate vaccine or PRP-OMP (PedvaxHIB), Hib tetanus toxoid conjugate vaccine or PRP-T (ActHIB and Hiberix).[56] The immunogenicity of the conjugate vaccines are age-dependent (i.e., older children have an improved immune response).[51],[55] The three conjugated vaccines are all approved for use in infants, the group at greatest risk for H. influenzae infection; however, they vary in their dosing regimens. The HbCV immunization series requires a priming series followed by a booster dose at 12 to 15 months. PRP-OMP's primary series is administered at 2 and 4 months of age in contrast to a schedule of 2, 4, and 6 months' primary series for the other vaccines.[1],[27],[56] Ideally, the primary series should be completed with the same HbCV; however, data support the interchangeability of the products for the priming and booster doses.[27],[56] If PRP-OMP is used in a priming series with another HbCV, the number of doses necessary to complete the series for the other product should be administered.[56] Combination vaccines may also be used according to indications for each (see Table 64-2).[27],[56]

The number of doses of HbCV vaccine needed in previously unimmunized older infants and children depends on their age at presentation. Children who begin HbCV at 7 to 11 months of age should receive a primary series of two doses of a vaccine containing PRP-T, or PRP-OMP followed by a booster dose at 12 to 18 months of age administered at least 2 months after the previous dose.[27],[56] Children aged 12 to 15 months should receive a primary series of one dose followed by a booster dose 2 months later. If a child reaches 15 months of age without receiving HbCV, only one dose is necessary.[27],[56] HbCV is not routinely recommended in children younger than 5 years of age or adults. Adults who have anatomical or functional asplenia or sickle cell disease, or are undergoing elective splenectomy should receive 1 dose of Hib vaccine if they have not previously received Hib. Adults with a hematopoietic stem cell transplant (HSCT) should receive 3 doses of Hib in at least 4-week intervals 6 to 12 months after transplant regardless of their Hib history. Hib is not routinely recommended for adults with human immunodeficiency virus infection because their risk for Haemophilus influenzae type b infection is low.

Polio

Polio, an infectious disease caused by a highly contagious enterovirus, can strike at any age, but primarily affects children younger than 3 years of age (>50% of cases). The three identified serotypes of poliovirus are transmitted person to person by direct fecal–oral contact or indirect exposure to infectious saliva, feces, or contaminated water.[57,58] After household exposure, 90% of susceptible contacts become infected.[57] The poliovirus enters through the mouth and then multiplies in the throat and intestines. Once established in the intestines, poliovirus can enter the bloodstream and invade the CNS, which may result in paralysis.[57–59]

Immunity to polio can be achieved after natural infection with poliovirus; however, infection by one serotype of the poliovirus does not protect an individual against infection from the other two serotypes.[57] Immunity can also be achieved through immunization, and the development of effective vaccines to prevent paralytic polio was one of the major medical breakthroughs of the 20th century. Since the advent of the trivalent oral polio vaccine (OPV) and inactivated polio vaccine (IPV), the incidence of paralytic poliomyelitis has been reduced dramatically.[59]

CASE 64-8

QUESTION 1: H.G. is the mother of a 2-month-old infant who is surprised when the nurse brings in a polio vaccine injection. She remembers that she received an oral form of the vaccine as a child. Why is H.G.'s infant receiving a different form of polio vaccine than she received?

Historically, the live attenuated oral polio vaccine (OPV or Sabin vaccine) was the formulation of choice in the United States. Its advantages include low cost, ease of administration, and induction of lifelong immunity.[57] In addition, OPV provides a high level of gastrointestinal immunity, thus preventing the carrier state. The fecal shedding of the attenuated OPV virus after vaccination is also an effective way to immunize or boost the preexisting immunity in close contacts.[57,59] Despite these benefits, OPV carries the risk of vaccine-associated paralytic polio (VAPP), especially after the first dose in immunocompromised patients such as those with B-lymphocyte disorders (e.g., agammaglobulinemia, hypogammaglobulinemia).[58] In contrast to OPV, the enhanced IPV (IPOL), which is administered intramuscularly, has not been associated with VAPP or other reactions.[58,60] Although IPV provides similar systemic immunity as OPV, it induces less immunity in the gastrointestinal tract.[57,59] The risks of VAPP from OPV, despite its high efficacy, have resulted in the recommendation of IPV as the preferred dosage form for childhood immunization.[1,27,60]

The ACIP and AAP guidelines recommend that all children should receive four doses of IPV at ages 2 months, 4 months, 6 to 18 months, and 4 to 6 years. The first dose of vaccine should be administered no sooner than 6 weeks of life.[60] The last dose of the four-dose series should be administered after 4 years of age and at least 6 months after the previous dose.[27,60] Combination vaccines containing IPV are available and may be used to provide the initial four IPV doses. However, to ensure adequate immunity, it is recommended that an additional IPV booster be administered at 4 to 6 years, for a total of five doses[55] (see Table 64-2).

CASE 64-9

QUESTION 1: L.G. is a 28-year-old graduate student who is planning extensive travels through the African continent and is concerned about polio because she had not been immunized as a child. What would be a prudent immunization schedule for her if her trip includes travel to a polio-endemic area?

Routine poliovirus vaccination of persons older than 18 years of age is not necessary in the United States because US residents are at minimal risk of exposure. Vaccination, however,

---

should be considered for adults at high risk of polio exposure (e.g., travel to an area endemic for polio, close contact with children who will be receiving OPV, close contact with patients who may be excreting wild polioviruses, or work that requires handling poliovirus specimens).[59],[60] IPV is the vaccine of choice because adults have a higher incidence of VAPP from OPV than children. Ideally, L.G. should receive two doses of IPV, administered 4 to 8 weeks apart, followed by a third dose 6 to 12 months later. If exposure is likely in less than 8 weeks, two doses of IPV should be administered at least 4 weeks apart.[59] If L.G.'s travel must be undertaken on short notice (<4 weeks) she should receive one dose of IPV with receipt of the remaining doses at a later date according to schedule.[59] Even if L.G. had been immunized as a child, a single dose of IPV may be considered for booster effect.[59]

Currently, OPV is recommended only in special circumstances, such as vaccination to control outbreaks of paralytic polio, unvaccinated infants traveling in less than 4 weeks to areas endemic for polio, and children of parents who reject the number of vaccine injections.[59],[60] In parents who are concerned about the number of injections, OPV may be considered for the third and fourth vaccination after receiving systemic protection with IPV for the first two doses.[59] IPV is the only poliovirus vaccine that should be used in patients with an immunodeficiency disorder, those receiving immunosuppressive chemotherapy, or those living with a person who is known or suspected to have these conditions.[59],[60]

Meningococcus

CASE 64-10

QUESTION 1: J.C. is a 12-year-old girl who presents for a check-up with her pediatrician. In discussion, it is found that her cousin attends a university where an outbreak of meningococcal disease recently occurred.

Should she receive meningococcal vaccine?

After dramatic reductions of Streptococcus pneumoniae and H. influenzae type b strains of meningitis secondary to conjugate vaccines, Neisseria meningitidis has become a more prominent cause of bacterial meningitis. The ACIP recommends routine vaccination of adolescents, with first dose at age 11 to 12 years and a booster at 16 years, persons >2 months of age at increase risk for meningococcal disease, and patients in at-risk groups to control outbreaks.[61] Patients with increased risk for meningococcal disease include those with persistent complement deficiencies, functional or anatomic asplenia, travel to countries where meningococcal disease is hyperendemic or endemic, or who are at risk during an outbreak. Patients aged 2 months to 55 years not previously vaccinated should receive the vaccination if they have persistent complement deficiency, functional or anatomic asplenia, have HIV, are first-year college students in residential housing, travel to countries where meningococcal disease is hyperendemic or endemic, or who are at risk during an outbreak, or are microbiologists who are routinely exposed to N. meningitides.[61]

The two available meningococcal vaccine options include two different conjugated vaccines (MCV) covering serotypes A, C, Y, and W-135 of N. meningitides. The two conjugate vaccines available (Menactra and Menveo), both MCV4 conjugate vaccines, are indicated for individuals 11 to 55 years of age.[61] The ACIP recommends administration of this vaccine to all persons at 11 to 12 years of age (or at high school entry if there is no history of vaccination) and to unvaccinated college freshmen residing in dormitories. Additionally, as stated earlier, the ACIP recommends a booster dose around the age of 16 years, and a two-dose primary vaccination for patients with reduced response to a single dose.

Adverse effects (e.g., fever, headache, chills, malaise, and arthralgias) from both vaccines are similar and relatively rare; however, the Centers for Disease Control and Prevention (CDC) and FDA issued a warning regarding the potential for increased risk of Guillain–Barré syndrome in patients receiving the Menactra conjugate vaccine.[62] Over the course of a 16-month period beginning in June 2005, 15 cases were reported in the 11- to 19-year age group, and two cases in those older than 20 years of age. All patients recovered. Despite this apparent small increased risk of Guillain–Barré syndrome, current recommendations remain the same, but monitoring of this development will continue. No cases of Guillain–Barré syndrome have been reported with Menveo; however, surveillance is ongoing. At this time, J.C. should receive one of the two MCV4 vaccines and be advised to receive a booster dose at age 16.

Human Papillomavirus

CASE 64-11

QUESTION 1: J.S. is a 12-year-old girl who is healthy and not currently sexually active. Her mother and she would like background information including the role of the human papillomavirus (HPV) vaccine and recommendations for use of the vaccine in J.S.

HPV commonly infects the genital tract and is primarily transmitted by sexual contact. Infection with HPV has been associated with cervical cancer as well as other anogenital cancers (vulvar and vaginal cancers in females and penile cancers in males), anogenital warts, and recurrent respiratory papillomatosis, and it is estimated to be the most common sexually transmitted infection in the United States.[63–65] HPV affects both sexes with similar infection rates, and it is usually asymptomatic, unrecognized, or subclinical.[63],[66] Acute HPV infections typically resolve without clinical complications within 1 year; however, 10% to 15% of infections remain persistent and pose a risk of invasive cervical carcinoma and other anogenital carcinomas.[67] Although not all HPV infections cause cervical cancer, almost all (99%) cervical cancer in women is associated with a previous HPV infection.[64],[67] The majority of disease associated with HPV is caused by the HPV types 6, 11, 16, and 18, with HPV strains 16 and 18 accounting for 64% of invasive HPV-associated cancers[65] and approximately 50% of cervical cancer precursors.[69],[70] In contrast, HPV strains 6 and 11 account for the cause of 90% of genital warts and most cases of recurrent respiratory papillomatosis.[68],[71] Infection with one strain of HPV does not prevent infection from other strains; thus, repeated infections can occur through one's lifetime,[67] and those with prior HPV infections benefit from immunization as well.

Three vaccines are available for the prevention of HPV infection: a quadravalent product (Gardasil), a nine-valent product (Gardasil 9), and a bivalent product (Cervarix). The quadravalent product is active against HPV strains 6, 11, 16, and 18; the nine-valent product is active against these strains in addition to 31, 33, 45, 52, and 58. Both of these products are indicated for males and females aged 9 to 26 years.[65] The bivalent product is active against only HPV strains 16 and 18 and is indicated only for females 10 to 25 years old.[71] Gardasil is indicated for males for the purpose of prevention of genital warts and anal cancers.[72]

Routine vaccination with any HPV vaccine is recommended for female patients at 11 to 12 years of age and may begin at 9 years of age.[65] Vaccination at this age attempts to achieve an immune

response before the sexual debut[63] and involves a two-dose series administered at intervals of 0 and 6-12 months for patients initiating vaccine before 15 years old.[65] Immunization against HPV is 90% effective in reducing persistent HPV infections and 100% effective in preventing HPV-related diseases such as genital warts or lesions.[68],[71] The quadravalent and nine-valent vaccines are recommended for females aged 13 to 26 years, males 13 to 21 years, and it may be given to males 22 through 26 who are men who have sex with men or immunocompromised if they have not been previously vaccinated.[65] The bivalent vaccine is recommended for females aged 13 to 26 years.[65]

The current vaccination rates for HPV vaccination remain below goal for Healthy People 2020, despite various strategies to improve rates and reduce the burden of disease and cancer caused by HPV.[64] The CDC recommends immunization for adolescent girls, regardless of current sexual activity, to decrease the lifetime risk of cervical cancer and to protect against infection when the time comes that an individual chooses to become sexually active.[71] Based on the current recommendations, J.S. should receive the HPV vaccine.

Pneumococcus

CASE 64-12

QUESTION 1: M.T. is a 5-year-old boy with a history of asthma. His pediatrician recommends that he receive the pneumonia vaccine. What is the evidence behind this recommendation?

S. pneumoniae (pneumococcus) infection can cause meningitis, pneumonia, sinusitis, and otitis media, and it is a major source of illness and death among children and adults.[73–75] Infants, young children, and older patients are at highest risk for exhibiting pneumococcal infections.[73] The risk for disseminated pneumococcal infections is increased by underlying medical conditions (heart failure, chronic obstructive pulmonary diseases), chronic liver disease (e.g., cirrhosis), functional or anatomic asplenia (e.g., sickle cell disease, splenectomy), and acquired or inherited immunosuppressive conditions (e.g., HIV, cancer, immunosuppressive therapy).

Two pneumococcal vaccines are available: the original polysaccharide vaccine (Pneumovax, PPSV 23) and a conjugate-pneumococcal vaccine (Prevnar, PCV 13).[73],[74] Pneumovax contains 23 of the most prevalent or invasive purified capsular-polysaccharide antigens types of S. pneumoniae. Antibody response to Pneumovax is inconsistent in children younger than 2 years of age partially because the antigens included in Pneumovax protect against strains that typically cause adult disease, but not childhood disease. In contrast, the conjugate pneumococcal vaccines (Prevnar 13) improve immunogenicity and efficacy in infants and toddlers.[74] The PCV 13 vaccine provides protection against the thirteen pneumococcal strains that cause 90% of all pneumococcal invasive disease in children younger than 6 years of age.[76] ACIP recommends giving the conjugate 13 vaccine (PCV 13) to all children aged 2 to 59 months and children aged 60 to 71 months with underlying medical conditions that place them at high risk for experiencing pneumococcal disease or its complications.[74] Because M.T. has already passed the recommended age for vaccination and has asthma, he should receive the PCV 13 vaccine today.

Immunocompromised patients typically have an unreliable response to vaccines, but because of the potential benefits the pneumococcal vaccines should be administered. PCV 13 and PPSV23 is recommended for children 6 to 18 years old and adult patients >19 years old with immunocompromising conditions, functional or anatomic asplenia, cerebrospinal fluid leaks, or cochlear implants.[75],[77] In children, PCV 13 should be administered first, followed by PPSV 23 8 weeks later, and a second PPSV 23 dose 5 years later.[77] Similarly, PCV 13 should be administered first to adults aged 19 to 64 years with immunocompromising conditions, followed by PPSV 23 8 weeks later, with a second PPSV 23 dose 5 years later. Additionally, adults who received PPSV 23 before 65 years old should receive another PPSV 23 dose at 65 years old, or later if it has been 5 years since their last PPSV 23.[75]

CASE 64-12, QUESTION 2: M.T.'s grandfather is a 68 years old who is a previous smoker and has cardiovascular disease. Should M.T.'s grandfather receive pneumococcal vaccine?

In the adult population, PCV 13 and PPSV 23 are recommended for patients over the age of 65 years and older.[78] Since S. pneumoniae causes significant morbidity and mortality within the elderly population, the PCV 13 vaccine was studied for efficacy in preventing pneumococcal community acquired pneumonia, non-bacteremic and invasive community acquired pneumonia, and invasive pneumococcal disease.[79] The PCV 13 vaccine was found to prevent pneumococcal, bacteremic, and non-bacteremic community-acquired pneumonia, but it failed to show a prevention of community-acquired pneumonia from any cause. The Centers for Disease Control and Prevention recommend adults >65 years old who have not received a pneumococcal vaccine receive a dose of PCV 13 followed by a dose of PPSV 23 6 to 12 months afterward.[78] The vaccines cannot be coadministered, and the minimum interval between the two vaccines should be at least 8 weeks. For patients >65 years old who have already received a PPSV 23 vaccine should also receive a PCV 13 vaccine >1 year after the most recent PPSV 23. If a second PPSV 23 is indicated, then the PPSV 23 should be administered 6 to 12 months after the PCV 13 or >5 years since the most recent PPSV 23. The 23-valent pneumococcal polysaccharide vaccine (Pneumovax) is also recommended for patients aged 19 to 64 years with certain underlying medical conditions.[73] These underlying medical conditions include immunocompetent patients with chronic heart disease, chronic lung disease, diabetes mellitus, cerebrospinal fluid leaks, cochlear implants, alcoholism, chronic liver disease, functional or anatomic asplenia, cigarette smoking, or who reside in nursing homes or long-term care facilities.[28–30,73] Specifically, adult patients with asthma and those who are cigarette smokers are proven to benefit from the pneumococcal vaccine.[73] A second dose of the vaccine should be administered 5 years after the first dose in patients 19 to 64 years old with functional or anatomic asplenia or who are immunocompromised who received the initial pneumococcal vaccine prior to 65 years of age.[73] If a patient is uncertain as to the accuracy of their vaccination, or when they received it, they should not receive revaccination because of lack of clinical evidence regarding the benefit of revaccination safety and benefit.[73] M.T.'s grandfather (a previously unvaccinated 68-year-old man) should receive one dose of PCV 13, followed by a dose of PPSV 23 6 to 12 months after receiving the PCV 13 vaccine.

Influenza

Annual influenza vaccination is the most effective method for preventing influenza viral infections, complications, and sequelae.[80] Recommendations for influenza vaccination include anyone older than 6 months of age who does not have a contraindication.[81] Routine vaccination has been supported since 2010, and clinical evidence confirms that annual influenza vaccination is a safe and effective preventative health measure with potential benefit for all ages of the population.[81] Vaccination should occur before the onset of influenza virus within the community and patients should receive their dose as soon as available.

Each year, the influenza vaccine is formulated to contain three or four inactivated influenza virus strains (usually, two type A and one or two type B) predicted to be in circulation within the United States during the upcoming flu season.[81] The vaccine is available in intramuscularly administered formulations including the following: inactivated vaccine (IIV) in both trivalent and quadrivalent standard-dose formulations, a trivalent recombinant hemagglutinin influenza vaccine (RIV3), a trivalent cell-cultured based inactivated vaccine (ccIIV3), and a trivalent inactivated high-dose formulation. There is a standard-dose trivalent intradermal inactivated vaccine and a quadrivalent intranasal live attenuated influenza vaccine (LAIV4).[81] Each season the composition of the vaccine is evaluated, and the trivalent formulations contain two influenza type A strains with one type B strain, whereas the quadrivalent formulations contain two type A strains and two type B strains.[80]

The injectable IIV is indicated for use in children at least 6 months old to adults, including those with high-risk conditions.[81] The LAIV4 (intranasal) is indicated for use in healthy nonpregnant patients aged 2 to 49 years old.[81] In patients over 18 years with a history of anaphylactic egg allergy, the trivalent recombinant influenza vaccine (RIV3) and the cell-cultured based inactivated influenza vaccine (ccIIV3) are considered safe for use.[81]

Influenza vaccine should be administered annually for adequate protection. Children younger than 9 years of age require two doses of the vaccine administered 1 month apart to achieve adequate antibody response during the first season they are vaccinated.[81] Influenza vaccine contains a small amount of egg protein, and historically it has been contraindicated in patients with a severe egg allergy.[81] Evidence indicates that even patients with severe egg allergies, including hives, or those who can eat lightly cooked eggs can safely receive the influenza vaccine in the setting of health care personnel in case anaphylactic treatment is necessary. The RIV3 and ccIIV3 are alternatives to patients with egg allergies.

The intradermal IIV is recommended for patients aged 18 to 64 years delivered via a microinjection system into the dermis.[81] Increased injection site reactions occur with this formulation compared to the intramuscular route.[81]

CASE 64-13

QUESTION 1: H.N. is a 72-year-old man inquiring about a new high-dose influenza vaccine. Is this a recommended vaccine for H.N.? Could he be given the LAIV instead?

A high-dose IIV (Fluzone High-Dose) is indicated for patients aged 65 years and older. Standard-dose inactivated trivalent influenza vaccines contain a total of 45 mcg (15 mcg of each of the three recommended strains) of influenza virus hemagglutinin antigen per 0.5-mL dose. In contrast, Fluzone High-Dose has 4 times the activity and is formulated to contain a total of 180 mcg (60 mcg of each strain) of influenza virus hemagglutinin antigen in each 0.5-mL dose. The older than 65 population is targeted to receive the high-dose formulation because older patients respond with a lower antibody titer to the conventional IIV.[82] When antibody titers were measured after patients received the high-dose vaccine, significantly higher antibody titers for all three influenza strains were present.[83–85] In a study to confirm that the high-dose influenza IIV improves protection against laboratory confirmed illness, the high-dose IIV produced higher antibody response and provided improved protection compared to the standard-dose IIV.[86] The high-dose recipients rates for pneumonia, cardiorespiratory conditions, hospitalizations, non-routine medical visits, and medication use were lower than the standard-dose recipients, thus concluding an estimate of improved relative efficacy for the high-dose IIV versus the standard-dose IIV.

The LAIV4 (FluMist) is available for use in healthy, nonpregnant patients 2 to 49 years of age. After administration, recipients become infected with attenuated virus strains, which stimulates both local IgA and circulating IgG antibodies.[87–90] Because live attenuated influenza viral particles are present within the LAIV4, recipients may experience mild signs or symptoms related to influenza infection, such as rhinorrhea, nasal congestion, fever, or sore throat.[91] The LAIV4 is indicated for nonpregnant patients aged 2 to 49 years old without medical conditions that predisposes to complications from the influenza virus. However, the LIAV is not recommended to be preferenced for use over the use of IIV3 at this time.[81] Individuals who should not receive or may not be able to receive the live vaccine include patients[92]:

- with a severe allergy to eggs, or inactive ingredients monosodium glutamate, gelatin, arginine, sucrose, dibasic potassium phosphate, monobasic potassium phosphate, or gentamicin

- with previous life-threatening reactions to previous influenza vaccinations
- currently wheezing or have a history of wheezing if under 5 years of age
- pediatric and adolescent patients currently taking aspirin therapy
- known or suspected immunodeficiency
- history of Guillain–Barré syndrome
- have a history of heart, kidney, or lung disease or diabetes
- are pregnant or nursing

Because of his age, HN should not be given the intranasal vaccine, but he could receive either the standard or high-dose inactivated vaccine.

LIVE ATTENUATED VACCINES

Besides the live attenuated flu vaccine discussed previously, there are several other live attenuated vaccines currently available for use (Table 64-1).

Rotavirus

Rotavirus is a major cause of gastroenteritis and subsequent dehydration in the United States. Almost all children in the United States will experience rotavirus gastroenteritis within the first 5 years of their lives and up to 50% of hospitalizations secondary to gastroenteritis in children are caused by rotavirus infection.[93],[94] The AAP and the CDC currently recommend routine immunization of infants with the rotavirus vaccine.[27] There are two oral, live attenuated rotavirus vaccines currently commercially available: Rotateq (RV5), a pentavalent vaccine, and Rotarix (RV1), a monovalent vaccine.[95] Both vaccines are believed to be equally effective despite lack of head-to-head comparison trials. The RV5 vaccine is administered in a three-dose series at 2, 4, and 6 months, whereas the RV1 vaccine follows a two-dose series at 2 and 4 months.[95] Initial vaccination should begin at a minimum of 6 weeks of age and the maximum age at which to administer the last dose is at 8 months of age.[95] It is preferred that all doses be administered with the same product; however, if a combination of RV5 and RV1 is used, a total of three doses should be administered.[95] Although immunization against rotavirus does not prevent all future episodes of rotavirus infection, it can significantly reduce the severity of infections and reduce hospitalization rates.

CASE 64-14

QUESTION 1: J.M., a 24-year-old mother, presents her 2-month-old infant to receive immunizations. She is concerned about the administration of the rotavirus vaccine because the infant's grandmother is undergoing chemotherapy for breast cancer, and she is concerned that the vaccine may put her mother at risk for infection as well as cause “bowel problems” for her baby.

Because the rotavirus vaccine is a live attenuated vaccine and infants can shed the virus after administration, the immunocompromised person (the grandmother) should avoid contact with the infant’s feces and adhere to good handwashing procedures, particularly during the first week after vaccine administration.[93–95] Although an immunized infant can spread the rotavirus to an immunocompromised person, the risk is believed to be small relative to the benefits and risks to the immunocompromised individual. For example, if not immunized the infant may become infected with rotavirus and shed much higher amounts of the virus in their stool with a greater potential of spreading the illness to others. Thus, rotavirus immunization of infants under this circumstance still is strongly encouraged.[93]

The immunization of infants who themselves are immunocompromised is more controversial. Rotavirus immunization in this circumstance requires the medical practitioner to discuss risks and benefits with the infant’s parents.

Despite being a live attenuated vaccine, the rotavirus vaccine may be administered at any time relative to the administration of blood products and antibody-containing products.[95] There appears to be no interference with the antibody response to the vaccine with the use of these products because much of the immune response is local within the gastrointestinal tract, which leads to protection from gastroenteritis.

Measles/Mumps/Rubella

CASE 64-15

QUESTION 1: J.C. is a 15-month-old girl who is scheduled to receive her MMR vaccination. J.C.’s mother is concerned about the risks of autism and other adverse effects from the vaccine. How should the mother be counseled?

Measles, historically a highly contagious and common disease of childhood, often is associated with symptoms such as high fever, rash, cough, rhinitis, and conjunctivitis.

Complications, although uncommon, include pneumonia and encephalitis. Live attenuated measles virus vaccine produces a benign infection that is thought to produce lifelong immunity. Infections with measles, mumps, or rubella are uncommon in the United States secondary to a significant decrease in the incidence of measles when American children were required to receive the vaccine before entering school.[96],[97] During the 1985 to 1988 epidemic, most measles transmission occurred in areas with 95% immunization rates, indicating that some children fail to respond adequately to the initial vaccine dose.[98] In addition, up to 47% of reported cases of measles in the United States result from international importation; the remaining cases result from outbreaks in school-age children who did not receive a second dose of the vaccine.[97],[99] Unfortunately, many parents are refusing immunization of their infants with the MMR vaccine because of media reports (now proven unfounded) about the risk of autism.

The concern regarding the risk from autism after vaccination with the MMR vaccine stems from a report by Wakefield et al. published in 1998. This report identified a causal relationship with the administration of the MMR vaccine and the subsequent development of autism in 12 children.[100] The results of this report became highly publicized and sparked fear in parents across the world. Further investigation revealed numerous counts of scientific misconduct for financial gains by Dr. Wakefield, which led to 10 of the 12 coinvestigators retracting their claims. The CDC has coordinated numerous investigations to uncover any relationship between the vaccine and autism, but despite years of research have been unable to find any association. Regrettably, efforts to counter the negative publicity for the MMR vaccine have not had success.

J.C.'s mother should be counseled regarding the lack of an association between autism and the MMR vaccine. If she still decides to refuse vaccination, appropriate forms for documenting such are available through the respective state's Department of Health.

The first dose of the MMR vaccine should be administered to children at 12 to 15 months of age, followed by a second dose at entrance to grade school (age 4 to 6 years).[1],[27],[97] Studies indicate that infants receiving the vaccine may be at higher risk of exhibiting a febrile seizure during the 2 weeks after vaccination when peak virus replication occurs.[101] The risk appears to be higher with the combination vaccine ProQuad. Because of this concern, the CDC recommends the preferential use of the MMR vaccine in children aged 12 to 47 months. Although studies have not shown a benefit with the use of antipyretics for preventing febrile seizures from the vaccine, it is recommended that caregivers be counseled regarding the management of fever. No increased risk of febrile seizures has been noted with the second dose of the vaccine administered at 4 to 6 years of age, thus the use of the combination vaccine is recommended at this age to reduce the number of injections and enhance compliance.[97]

Adult vaccination with MMR vaccine is also important to protect from epidemics. Adults should receive a second dose of MMR if they were born between 1963 and 1967, previously vaccinated with killed measles vaccine, are students in postsecondary institutions, work in health care facilities, travel internationally, or were recently exposed to a measles outbreak.[97] Persons born after 1957 should receive one dose of a measles-containing vaccine.[28–30,97] Health care workers must show documentation of having receipt of the appropriate number of doses or laboratory evidence of immunity to comply with infection control policies.[102]

Mumps and rubella antigens are combined with measles in the MMR vaccine in the United States. Mumps illness in children rarely produces complications.[97] Meningoencephalitis generally is a benign meningitis, and postinfectious encephalitis, a serious complication, is extremely rare (1 of 6,000). Deafness, commonly considered a risk of mumps, occurs rarely (1 of 15,000) and is usually unilateral. Orchitis, another complication, occurs in approximately 3% to 10% in postpubertal males since the postvaccine era and rarely causes sterility. The most significant consequences of rubella infection occur in pregnant women (e.g., spontaneous abortions, miscarriages, stillbirths, fetal anomalies), especially when infection occurs during the first trimester.[97]

Varicella

CASE 64-16

QUESTION 1: J.T. is a 6-year-old girl who comes home from school with a note from the school nurse indicating that a child in her kindergarten class has been diagnosed with chickenpox. J.T.'s mother is quite concerned because J.T. has not been immunized with the varicella vaccine. She wants to know whether administration of the vaccine at this time will protect J.T. from becoming infected.

Varivax, a live attenuated vaccine against varicella-zoster (chickenpox), is the first herpesvirus vaccine to be widely tested in healthy and high-risk children and adults.[103–105] Chickenpox is a highly contagious, mild childhood disease in healthy children, but it can be severe and even fatal, especially in the immunocompromised patient.

Unusual complications (e.g., severe bacterial superinfections, Reye syndrome, encephalopathies) are markedly reduced with an immunization program.[103] Before the vaccine was available, approximately 4 million cases of chickenpox were reported annually, with 4,000 to 9,000 hospitalizations and 100 deaths.[103] Historically, 55% of varicella-related deaths occurred in adults, many of whom were infected by exposure to unvaccinated preschool-aged children with typical cases of varicella.[106]

Despite high vaccine coverage rates and 85% vaccine efficacy with the previous single dose vaccination, outbreaks of breakthrough varicella continued to occur in the United States.[107] As a result, current guidelines recommend a two-dose series for all children, adolescents, and adults without evidence of immunity.[1],[27],[107] The first varicella vaccine dose should be administered at 12 to 15 months of age, followed by the second dose at 4 to 6 years of age. For persons 7 to 12 years of age who have not received varicella vaccine, two doses of varicella vaccine should be administered at least 3 months apart. For persons older than 13 years of age, administer two doses of varicella vaccine at least 4 weeks apart.[107]

Postexposure varicella vaccination should be considered for J.T. Chickenpox infection can be prevented or symptoms reduced if varicella vaccine is administered within 3 days of exposure and may provide some protection within 5 days.[105],[107] If J.T. also needs MMR vaccination, the quadrivalent combination vaccine ProQuad containing measles, mumps, rubella, and varicella antigens may be considered. A second dose of varicella vaccine in 3 months should be recommended to ensure long-term protection.

The most common adverse effect associated with varicella vaccine administration is rash. Transmission of the virus from the vaccine has been documented in only 3 of 15 million doses administered, all of which occurred in the presence of a vesicular rash after vaccination.[103] Caution should be used when patients exhibit a rash postvaccination to avoid contact with immunocompromised individuals until rash resolution.[107]

Although varicella vaccine might not entirely prevent the occurrence of chickenpox in an immunocompromised patient, it can modify the disease. In the National Institutes of Health's Collaborative Varicella Vaccine Study, a seroconversion rate of only 85% was observed after a single dose in adults, compared with 95% in healthy children and 90% in children with leukemia.[108] Varicella vaccine is generally not recommended in children who have cellular immunodeficiencies, but it can be used in those with impaired humoral immunity.[107] The vaccine should be avoided in children with symptomatic HIV, but it may be considered in asymptomatic or mildly symptomatic patients.[103],[107]

CASE 64-16, QUESTION 2: If the varicella vaccine is now universally recommended, what is the role of the herpes zoster vaccine?

After a primary infection with varicella, 15% to 30% of the population experiences a latent infection in the sensory nerve ganglia that reactivates, causing herpes zoster (HZ).[107],[109] HZ typically occurs decades after initial varicella infection. This reactivation can result in post-herpetic neuralgia or dissemination which results in skin eruptions ("shingles") and potential CNS, pulmonary, or hepatic complications.[107],[109] Although some have theorized that universal varicella vaccination should eventually reduce the incidence of HZ because it prevents primary infection, others debate that the attenuated virus may have greater potential for becoming latent and reactiving.[107],[109] Still others argue that with the elimination of wild-type virus in the community, the exposure of individuals with latent wild-type varicella to help boost immunity and prevent HZ is reduced. In this situation, the risk of HZ may be increased.[107],[109] Routine varicella immunization began in 1995 and only long-term studies of vaccinated individuals will answer the questions about the impact of the varicella vaccination upon the incidence of HZ. However, currently the majority of adults are not immunized against varicella (unless required as a health care worker) and have previously acquired wild-type varicella infections. Therefore, most adults in the United States are at risk for exhibiting HZ as they age.

The zoster vaccine (Zostavax) is a live attenuated varicella zoster vaccine that uses the same strain and antigens as the varicella vaccines (Varivax and ProQuad); however, it is 14 times more potent and contains additional antigenic components. It was initially recommended for all individuals older than 60 years of age as a single subcutaneous injection to prevent HZ.[28–30,109,110] In 2011, FDA approval was given to use HZ vaccine in individuals 50 years of age or older; however, ACIP recommendations remain for patients 60 years and older.[110] It may be given to patients with a previous history of HZ, but it is not indicated to treat acute zoster or prevent further complications during an acute episode.[109] It is not recommended for routine immunization for anyone who has previously received the varicella vaccine. The zoster vaccine was shown in the Shingles Prevention Study to reduce the incidence of HZ by more than 50% and resulted in reductions in the severity and duration of pain, in addition to preventing the development of post-herpetic neuralgia.[111]

ADMINISTRATION TECHNIQUES

Vaccines or other biological agents are typically administered as either an intramuscular (IM) or subcutaneous injection.

Because appropriate administration by the correct route and technique is critical to the effectiveness of the specified vaccine, it is essential to consult the prescribing and administration information for each specific vaccination administered to a patient (see also Table 64-1). The technique of vaccine administration by either route should include sterilizing the skin surface, drawing up the vaccine from the vial into a syringe using sterile technique, protecting the patient and health care provider regarding biological hazards, performing proper disposal of biohazardous/sharps materials (needles and blood-borne products), observing for adverse effects after administration, and reassuring the patient postvaccine administration. Table 64-3 includes general guidelines for safe and effective parenteral administration.

CASE 64-17

QUESTION 1: B.D., a nurse from a family medicine clinic, frantically calls you because she mistakenly administered a Pneumovax vaccination subcutaneously. How to you respond to B.D.'s call?

The majority of vaccines, including Pneumovax, specify IM administration. This technique involves penetration of the appropriate muscle at a 90-degree angle. For graphical illustration of intramuscular vaccine administration, see http://www.immunize.org/catg.d/p2020.pdf. Site of IM injections include the anterolateral thigh muscle in infants and toddlers, and the deltoid (upper arm) muscle for children and adults.[1],[112] The typical needle used to administer an IM injection is 1 inch long and 22 to 25 gauge. A shorter needle (e.g., 5/8 inch) may be used for newborns, whereas a 1 to 1/2-inch needle may be needed for adults weighing greater than 90 kg for women and 118 kg for men.[112,113] Multiple IM injections given in the same extremity during the same time period should be placed at least 1 inch apart.[1] Although most vaccine products specify the route of administration, Pneumovax may be administered either IM or into subcutaneous tissue.[114] Therefore, B.D. should be reassured that she has administered the Pneumovax correctly because it is acceptable to administer this vaccination by either route.

Table 64-3

Subcutaneous and Intramuscular Vaccine Administration Techniques

Patient Age	Site	Injection Area	Typical Needle Length (inch)	Needle Gauge
Birth to 12 months	Subcutaneous	Fatty tissue over the anterolateral thigh muscle	5/8	23–25
12 months and older	Subcutaneous	Fatty tissue over anterolateral thigh or fatty tissue over triceps	5/8	23–25
Newborn (0–28 days)	Intramuscular	Anterolateral thigh muscle	5/8	22–25
Infant (1–12 months)	Intramuscular	Anterolateral thigh muscle	1	22–25
Toddler (1–3 years)	Intramuscular	Anterolateral thigh muscle OR Deltoid muscle of arm if muscle mass is adequate	1–1¼ 5/8–1	22–25
Children (3–18 years)	Intramuscular	Deltoid muscle OR Anterolateral thigh muscle	5/8–1 1–1¼	22–25
Adults ≥19 years	Intramuscular	Deltoid muscle OR Anterolateral thigh muscle	1–1½	22–25

Sources: National Center for Immunization and Respiratory Diseases. General recommendations on immunizations-recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR Recomm Rep. 2011;60:1–61; Immunization Action Coalition. How to Administer Intramuscular (IM) Vaccine Injections. **http://www.immunize.org/catg.d/p2020.pdf**. Accessed May 27 2015; Immunization Action Coalition. Administering Vaccines: Dose, route, site, and needle size. **http://www.immunize.org/catg.d/p3085.pdf**. Accessed May 27 2015.

Subcutaneous vaccinations involve injection of vaccine into fatty subcutaneous tissue between the layer of skin and the layer of muscle.[1,112] Subcutaneous vaccinations are administered with a 5/8-inch needle, 23 to 25 gauge, inserted at a 45-degree angle to the skin, while pinching up on the subcutaneous tissue to prevent injection into the muscle. For graphical illustration of subcutaneous vaccination administration, see **http://www.immunize.org/catg.d/p2020.pdf**. Sites of subcutaneous injections include the fatty tissue over the anterolateral thigh muscle in children newborn to 1 year old, and fatty tissue over the triceps in children 1 year old to adults. Multiple subcutaneous injections given in the same extremity during the same time period should be placed at least 1 inch apart.

Other routes of administration for vaccinations include the oral, intranasal, and intradermal routes. Rotavirus and oral typhoid are the only orally administered vaccines in the United States.[1] Inactivated influenza is the only intranasal vaccine, administered via a nasal sprayer with a dose divider. Intradermal influenza is the only intradermally administered vaccine, and it is administered in the area of the deltoid at a 90-degree angle into the skin.[113]

LEGAL REQUIREMENTS

CASE 64-18

QUESTION 1: What are the requirements necessary to become a pharmacist immunizer? How are pharmacists advocates for improving population immunization rates?

Pharmacists have varying authority to administer vaccinations within the United States based on each state's Pharmacy Practice Act. The rationale for pharmacists to deliver immunizations to the public includes pharmacist accessibility in every community and overall low vaccination rates throughout the population.[115] The Department of Health & Human Services and Centers for Disease Control and Prevention recognized pharmacist's unique position to promote vaccines and also influence vaccination in diverse populations through a letter from the Assistant Surgeon General.[116] This letter also acknowledged pharmacist's contribution to increase immunization awareness in the past, but it also requested continued assistance in this endeavor through the following:

- Increasing vaccine awareness in the adult and adolescent population
- Ensuring patient's vaccine requirements are assessed when they visit pharmacies
- Offering vaccinations to patients with certain medical conditions (high risk)
- Entering adult immunizations into vaccine registries where possible
- Partnering and collaborating with local and state health departments, immunizatio coalitions, medical providers, and other vaccination outreach programs

The American Pharmacist's Association has developed a national competency-based certificate training program for pharmacists, and most schools of pharmacy across the country contain or provide an opportunity to learn immunization administration within their curriculum.[117] These programs include both didactic and hands-on training and prepare the learners to be public health educators regarding immunizations, to promote vaccinations within their community, and to administer vaccines at their practice sites.

Although each state's requirements regarding necessary training, protocols, and notification systems may differ, there are some standardized requirements a pharmacist immunizer must follow. Current cardiopulmonary resuscitation certification is a common requirement for pharmacist immunizers. Immunization administration curricula typically contain information regarding basic immunology, specifics regarding vaccine information, practice implementation, legal and regulatory issues, and administration techniques.[117] Each state stipulates the statutes on patient age that may receive a pharmacist-administered vaccination; what types of vaccinations pharmacists are able to administer; and the mechanism by which pharmacists are authorized to administer vaccines by physicians, such as through a prescription, collaborative drug therapy management agreement, protocol, or standing order.[118] Some states require continuing-education credit maintenance specific to immunizations or vaccinations for pharmacists who immunize; some states are very specific in their requirements, and others are more general. It is important to check with the state licensing board regarding specific statutes and regulations relating to pharmacist immunization practices. In addition, a growing number of states have passed legislation allowing pharmacy interns with the necessary training to administer immunizations. Currently, 44 states and territories have adopted legislation allowing pharmacy interns to administer vaccines, given the student has completed an immunization certificate program and operates only under supervision of an immunizing pharmacist.[118]

Patient consent forms for immunization and vaccine information sheets are important aspects for patient safety that pharmacists are required to use as part of an approved immunization program. Consent forms should include screening questionnaires specific for each vaccine, should be signed prior to vaccine administration, and should be reviewed by the pharmacist with the patient present. Vaccine information sheets are patient information developed by the CDC providing specific individual vaccine information benefits and risks, and they are required to be distributed to the patient with each vaccine by the National Childhood Vaccine Injury Act of 1986. Resources for pharmacists are available through the CDC, Immunization Action Coalition, and American Pharmacists Association.[119–121]

Central Nervous System Infections

Gregory A. Eschenauer, Deanna Buehrle, and Brian A. Potoski

CORE PRINCIPLES		CHAPTER CASES
1	The most common symptoms of meningitis include the triad of fever, stiff neck, and altered mental status. In neonates and infants, irritability and poor feeding may be reported along with fever. In the elderly, signs may be absent or more subtle.	**Case 65-1 (Question 1)**
2	Adjunctive dexamethasone should be initiated in all patients with suspected bacterial meningitis either before or concomitant with the first dose of antibiotic.	**Case 65-1 (Question 4)**
3	Intraventricular antibiotics should be considered for patients with meningitis who have an external drainage device in place. Such therapy should be used in combination with systemically administered therapy.	**Case 65-4 (Question 4)**
4	Cerebrospinal fluid (CSF) is essential in confirming the diagnosis of meningitis. The CSF typically contains many white blood cells (WBCs) with a predominance of neutrophils. Additionally, CSF protein is typically elevated to greater than 100 mg/dL with a low CSF glucose concentration (either less than 50 mg/dL or less than 50-60% of a simultaneously obtained serum glucose value).	**Case 65-1 (Question 2)**
5	Response to therapy should be monitored by resolution of fever, altered mental status, and stiff neck. A baseline level of mental status should be evaluated for this reason. Delays in response to therapy may require a repeat lumbar puncture to re-examine CSF cultures, which are usually sterile after 18 to 24 hours of therapy. Clinical response should be seen between 24 and 48 hours of initiation of therapy.	**Case 65-1 (Question 6)**
6	The choice of empiric therapy in patients with meningitis is primarily driven by age and the presence of predisposing conditions (postneurosurgical, head trauma, immunocompromised).	**Case 65-1 (Question 3)**
7	Brain abscess is associated with a different spectrum of pathogens, including oral anaerobes, staphylococci, and aerobic gram-negative bacilli, depending on the patient. The barrier from the blood to brain parenchyma differs from that between blood and CSF. Consequently, the choice of antimicrobial for brain abscess may differ from that associated with meningitis.	**Case 65-5 (Questions 1–3)**

The pharmacotherapy of central nervous system (CNS) infections presents numerous challenges. Antibiotic penetration often is limited, and host defenses are absent or inadequate. Thus, morbidity and mortality from infections of the CNS remain high despite the availability of highly potent, bactericidal antibiotics. In a review of 3,155 episodes of bacterial meningitis between 1998 and 2007, the mortality rate was 15%.[1] Although eradication of bacteria is essential, it is only one of the variables that affect mortality from CNS infections. In an attempt to decrease morbidity and mortality, the pathophysiologic mechanisms of CNS infections continue to be studied.[2]

A number of infectious processes can occur within the CNS (e.g., meningitis, encephalitis, meningoencephalitis, brain abscess, subdural empyema, and epidural abscess). In addition, prosthetic devices placed into the CNS (e.g., CSF shunts for management of hydrocephalus) often are complicated by infection. Many etiologic agents are capable of inducing CNS infections, including bacteria, viruses, fungi, and certain parasites. This chapter focuses primarily on bacterial infections of the CNS, with an emphasis on the pharmacotherapy of bacterial meningitis and brain abscess. (Also see Chapter 76, Pharmacotherapy of Human Immunodeficiency Virus Infection, and Chapter 77, Opportunistic Infection

in HIV-Infected Patients, for presentations pertaining to CNS infections in these populations).

REVIEW OF CENTRAL NERVOUS SYSTEM

Anatomy and Physiology

MENINGES

Proper therapy of CNS infections requires an understanding of anatomic and physiologic characteristics. The brain and spinal cord are ensheathed by a protective covering known as the meninges and suspended in CSF, which acts as a shock absorber to outside trauma. The meninges consist of three layers of fibrous tissue: the pia mater, arachnoid, and dura mater. The pia mater, the innermost layer of the meninges, is a thin, delicate membrane that closely adheres to the contours of the brain. Separating the pia mater from the more loosely enclosed arachnoid membrane is the subarachnoid space, in which the CSF resides. The pia mater and arachnoid, known collectively as the leptomeninges, lie interior to the dura mater, a tough outer membrane that adheres to the periosteum and vertebral column. Meningitis is a term describing inflammation (often the result of infection) of the subarachnoid space.

Abscesses also can form outside the dural space (epidural abscess), often with devastating consequences.[3]

CEREBROSPINAL FLUID

CSF is produced and secreted by the choroid plexus in the lateral ventricles and, to a lesser extent, by the choroid plexuses within the third and fourth ventricles. CSF flows unidirectionally from the lateral ventricles through the foramina of the third and fourth ventricles into the subarachnoid space, then over the cerebral hemispheres and downward into the spinal canal. CSF is absorbed through villous projections (arachnoid villi) into veins, primarily the cerebral venous sinuses. About 0.35 to 0.4 mL of CSF is secreted per minute, with 50% of the total volume of CSF being replaced every 5 to 6 hours.[4] The flow of CSF is unidirectional from the ventricles to the intralumbar space. Therefore, intrathecal injection of antibiotics results in little, if any, antibiotic reaching the cerebral ventricles.[3] This unidirectional flow of CSF presents a problem because ventriculitis commonly occurs in conjunction with bacterial meningitis. Direct intraventricular instillation of antibiotics, usually by means of a reservoir, is preferable in the setting of ventriculitis (see Case 65-4, Question 4).[5]

In adults, children, and infants, the volume of CSF is approximately 150 mL, 60 to 100 mL, and 40 to 60 mL, respectively.[4],[6] Knowledge of approximate CSF volume facilitates estimation of the CSF concentration of a drug subsequent to intrathecal administration. For example, administration of gentamicin 5 mg (5,000 mcg) intrathecally should result in a CSF concentration of approximately 33 mcg/mL in an adult shortly after administration.

The composition of CSF differs from other physiologic fluids. The pH of CSF is slightly acidic (normal pH, 7.3), and with the exception of chloride ion, electrolyte concentrations are slightly less than those in serum.[5] Under normal conditions, the protein concentration in CSF is 15 to 45 mg/dL, CSF glucose values are 50 to 80 mg/dL (approximately 60% those of plasma), and few if any WBCs are present (<5 cells/μL).[3] When the meninges become inflamed (i.e., in meningitis), the composition of the CSF is altered. In particular, the protein concentration in the CSF increases, and the glucose concentration in the CSF usually declines with meningitis. Therefore, careful evaluation of CSF chemistries is useful when establishing a diagnosis of meningitis.

BLOOD–BRAIN BARRIER

The blood–brain barrier plays a crucial role in protecting the brain and maintaining homeostasis within the CNS.[3],[4] Actually, two distinct barriers exist within the brain: the blood–CSF barrier and the blood–brain barrier. The blood–CSF barrier is characterized morphologically by porous capillaries (Fig. 65-1). This allows proteins and other molecules (including antibiotics) to pass freely into the immediate interstitial space. Diffusion of substances into the CSF is restricted by tightly fused cells lining the ventricular side of the choroid plexus (Fig. 65-1). Cerebral capillary endothelial cells make up the blood–brain barrier, which separates blood from the interstitial fluid of the brain. Unlike capillaries in other areas of the body, the capillary endothelia of the brain are packed closely together, forming tight junctions that in effect produce a barrier physiologically similar to a continuous lipid bilayer. The surface area of the blood–brain barrier is more than 5,000 times greater than that of the blood–CSF barrier; thus, the blood–brain barrier plays a more important role in protecting the brain and regulating its chemical composition.[7] Many antimicrobials traverse the blood–brain barrier with difficulty (see section on Antimicrobial Penetration Into the Cerebrospinal Fluid below).

MENINGITIS

Meningitis is the most common type of CNS infection. The signs and symptoms associated with bacterial meningitis usually are acute in onset, evolving over the course of a few hours. Prompt recognition and early institution of therapy are essential to ensuring beneficial outcomes.[8] In contrast, a diverse group of infectious (e.g., viruses, fungi, and mycobacteria) and noninfectious (e.g., chemical irritants) agents produce a meningitic picture often of a less acute or chronic nature.[9],[10] Drugs that can induce aseptic meningitis include trimethoprim–sulfamethoxazole (TMP-SMX), intravenous (IV) immunoglobulins, OKT3 antibodies, and nonsteroidal anti-inflammatory drugs such as ibuprofen, naproxen, and sulindac.[9]

Microbiology

Generally, meningitis is a disease of the very young and very old: Most cases occur in children younger than 2 years of age and in elderly adults.[1] The bacterial causes of meningitis correlate well with age and underlying conditions (Table 65-1).[11]

Neonates (infants <1 month) are at an especially high risk of experiencing meningitis. Meningitis in preterm neonates is most often caused by Escherichia coli whereas meningitis in term neonates is most often caused by group B streptococci (Streptococcus agalactiae). These highly virulent pathogens usually are acquired during passage through the birth canal or from the hospital environment and are associated with significant morbidity and mortality, particularly in premature infants.[1],[12] Consensus recommendations regarding intra-partum administration of penicillin to women colonized with group B streptococci have led to an 80% decrease in early-onset infection due to this pathogen.[13] Listeria monocytogenes is another important and often overlooked pathogen in neonates.[1] Because L. monocytogenes is resistant to many antimicrobial agents, including third-generation cephalosporins, selection of initial (empiric) therapy in neonates must be approached with this pathogen in mind.[11]

Table 65-1

Microbiology of Bacterial Meningitis

Age Group or Predisposing Condition	Most Likely Organisms[a]
Neonates (<1 month)	Group B streptococcus (Streptococcus agalactiae), Escherichia coli, Klebsiella species, Listeria monocytogenes
Infants and children (1–23 months)	Streptococcus pneumoniae, Neisseria meningitidis, S. agalactiae, Haemophilus influenzae,[b] E. coli
Children and adults (2–50 years)	N. meningitidis, S. pneumoniae
Adults (>50 years)	S. pneumoniae, N. meningitidis, L. monocytogenes, E. coli, Klebsiella species, and other aerobic gram-negative bacilli
Postneurosurgical	Staphylococcus aureus, aerobic gram-negative bacilli (e.g., E. coli, Klebsiella species, Pseudomonas aeruginosa), Staphylococcus epidermidis[c]
Closed head trauma	S. pneumoniae, H. influenzae, group A β-hemolytic streptococci
Penetrating trauma	S. aureus, S. epidermidis, aerobic gram-negative bacilli (e.g., E. coli, Klebsiella species, P. aeruginosa)
CSF shunt	Coagulase-negative staphylococci (particularly S. epidermidis), S. aureus, aerobic gram-negative bacilli (including P. aeruginosa), Propionibacterium acnes

[a] Organisms listed in descending order of frequency.

[b] Need to consider this pathogen only in children not vaccinated with Hib.

[c] Most commonly seen in association with prosthetic devices (e.g., cerebrospinal fluid shunts).

CSF, cerebrospinal fluid.

Infants and children 2 to 23 months old are also at a high risk of meningitis. Historically, in this age group, the disease was caused predominantly by three pathogens: Haemophilus influenzae, Streptococcus pneumoniae, and Neisseria meningitidis. Up to 45% of all cases of meningitis in the United States before 1985 were caused by H. influenzae type b (Hib).[14] From 1991 to 1996, however, Hib invasive disease incidence in children <5 years of age decreased by >99%. This reduction in H. influenzae-induced meningitis correlates with the widespread vaccination of children against invasive H. influenzae disease with the Hib polysaccharide–protein conjugate vaccines.[15]

In adults and children who have received the conjugated Hib vaccine, community-acquired meningitis most often is caused by S. pneumoniae (the pneumococcus) and N. meningitidis (the meningococcus). Meningococci more commonly are implicated in individuals aged 2 to 34 years, whereas pneumococci are the predominant pathogens in adults older than 34 years of age.[1] The incidence of pneumococcal meningitis has decreased by 26% from 1998 to 2006–2007 with the introduction of pneumococcal conjugate vaccines, with a decrease of 92% if only serotypes contained in the seven-valent conjugate vaccine are considered.[16] Unfortunately, use of the 13-valent conjugate vaccine has not resulted in further decreases in meningitis cases in children, with nonvaccine serotypes replacing those contained in the vaccine.[17] The incidence of meningococcal disease has decreased by 73% from 1996 to 2011. Interestingly, most of this decline in incidence occurred prior to the routine use of meningococcal conjugate vaccines.[18]

Patients of advanced age and those who undergo neurosurgical procedures or experience head trauma are also susceptible to meningitis. The most likely causative pathogens in these patient populations are listed in Table 65-1.

Pathogenesis and Pathophysiology

In general, meningitis can develop from hematogenous spread of organisms, by contiguous spread from a parameningeal focus (e.g., sinusitis or otitis media), or by direct bacterial inoculation, as occurs with head trauma or neurosurgery. In contiguous spread, colonization of mucosal surfaces is a necessary first step in the pathogenesis of meningitis. Meningeal pathogens then adhere to, and penetrate through, the epithelial surface and enter the intravascular space. Eventually, organisms multiply to sufficient numbers that allow invasion of the blood–brain barrier.[2],[19],[20]

Once bacteria gain entry into the CSF, host defenses are inadequate to contain the infection, and bacteria replicate rapidly. Humoral immunity (both complement and immunoglobulin) essentially is absent within the CSF. In addition, opsonic activity in CSF is negligible, and although leukocytosis ensues shortly after bacterial invasion, phagocytosis also is inefficient. Therefore, this relative immunodeficiency state necessitates the initiation of bactericidal therapy.[2],[19],[20]

Inflammation of the meninges is initiated by contents within the bacterial cell wall. Release of these contents (lipopolysaccharide for gram negatives and teichoic acid for gram positives) induces the production and secretion of inflammatory cytokines, which promote the adherence of leukocytes to cerebral capillary endothelial cells and facilitate the migration of leukocytes into the CSF. This results in the characteristic CSF leukocytosis as well as an eventual increase in blood–brain barrier permeability.[2],[19],[20]

Inflammation of the blood–brain barrier may lead to brain edema, which, combined with obstruction of CSF outflow, increases intracranial pressure and alters cerebral blood flow. Resultant hyperperfusion or hypoperfusion of the brain may ultimately result in neuronal injury, cerebral ischemia, and irreversible brain damage. The inflammatory response in meningitis also can be aggravated by some antibiotics, notably the penicillins and cephalosporins.[19] When the β-lactam antibiotics lyse bacterial cell walls, large amounts of cell wall products are liberated, and these products amplify the inflammatory response. The long-term benefits of β-lactam therapy far outweigh such detrimental effects, and the use of adjunctive corticosteroids in certain patient populations can substantially reduce inflammation and the subsequent neurologic sequelae of meningitis.[2],[19],[20]

In a systemic review of approximately three decades of data surrounding neurologic sequelae, the median risk of developing at least one major or minor sequela was 19.9% (12.3%–35.3%).[21] The type and severity of neurologic complications vary with the specific infecting organism, the severity of the infection, and the susceptibility of the host. In a long-term prospective study of 185 children with acute bacterial meningitis, permanent hearing loss occurred in 6%, 10.5%, and 31% of children with meningitis caused by H. influenzae, N. meningitidis, and S. pneumoniae, respectively. Although seizures are fairly common on initial presentation, long-term epilepsy occurs in approximately 7% of patients. Other important long-term complications include spastic paraparesis, behavioral disorders, and learning deficits.[22]

Diagnosis and Clinical Features

CLINICAL AND LABORATORY FEATURES OF BACTERIAL MENINGITIS

CASE 65-1

QUESTION 1: S.C., a 5-year-old boy, is brought to the emergency department (ED) by his mother, who says her son has a temperature of 39°C, is irritable and lethargic, and has a rash. S.C. was in his usual state of good health until last night, when he awoke crying. When she went to investigate, her son began to stiffen up and rock back and forth in his bed. Because he was not arousable, S.C.'s mother rushed him to the hospital. S.C.'s medical history is noncontributory except for an allergy to amoxicillin described as a skin rash. S.C., his mother and father, and his 7-year-old brother recently moved to the United States. S.C.'s vaccination history currently is unknown. S.C. and his brother currently attend a community day-care center.

On physical examination, S.C. was in marked distress, with a temperature of 40°C, blood pressure of 90/60 mm Hg, and a respiratory rate of 32 breaths/minute. His weight on admission was 20 kg. Neurologic examination showed evidence of nuchal rigidity; he was lethargic and difficult to arouse. Brudzinski and Kernig signs were positive. On head, eyes, ears, nose, and throat examination, S.C. demonstrated photophobia (he squinted severely when the examiner shone a light in his eyes), but no evidence was noted of papilledema. A petechial rash was visible on his extremities. The remainder of S.C.'s examination was essentially normal.

Blood drawn for laboratory tests revealed the following results:

Sodium (Na), 128 mEq/L
Potassium (K), 3.2 mEq/L
Chloride (Cl), 100 mEq/L
Bicarbonate (HCO_3), 25 mEq/L
Blood urea nitrogen (BUN), 16 mg/dL
Serum creatinine (SCr), 0.6 mg/dL
Serum glucose, 80 mg/dL

The WBC count was 18,000 cells/µL with 95% polymorphonuclear (PMN) cells; the hemoglobin (Hgb), hematocrit (Hct), and platelet count all were within normal limits. What clinical and laboratory features does S.C. display that are suggestive of meningitis?

Table 65-2

Signs and Symptoms of Acute Bacterial Meningitis

Fever	Anorexia
Nuchal rigidity (stiff neck)	Headache
Altered mental status	Photophobia
Seizures	Nausea and vomiting
Brudzinski sign[a]	Focal neurologic deficits
Kernig sign[a]	Septic shock
Irritability[b]	

[a] See text for description of sign.

[b] Symptoms seen in infants with meningitis.

The clinical features of bacterial meningitis are summarized in Table 65-2. The most common symptoms include the triad of fever, stiff neck (nuchal rigidity), and altered mental status. When all three of these features are present, as is S.C.'s case, meningitis should be strongly suspected. Other less common signs and symptoms include headache, photophobia (unusual intolerance to light), and focal neurologic deficits, including cranial nerve palsies.[23] A positive Brudzinski sign (reflex flexion of the hips and knees produced on flexion of the neck when lying in the recumbent position) and Kernig sign (pain on extension of the hamstrings when lying supine with the thighs perpendicular to the trunk) provide physical evidence of meningeal irritation.[24] Brudzinski and Kernig signs both were positive in S.C. Seizures occur on initial presentation in up to 60% of patients and may be focal or generalized.[23] The presence of seizures or a severely depressed mental status (i.e., obtundation or coma) generally is associated with a poorer prognosis.[25] According to the most recent practice guidelines for the management of bacterial meningitis, a computed tomographic (CT) scan should be obtained before lumbar puncture in patients with specific criteria. These include immunocompromised state, history of CNS disease, new-onset seizure, papilledema, abnormal level of consciousness, and focal neurologic deficit. Although controversial, brain herniation can occur when lumbar puncture is performed in patients with elevated intracranial pressure because of the pressure changes induced within the cranial vault.[11]

S.C. has many of the clinical features associated with acute bacterial meningitis. Furthermore, the low blood pressure (hypotension) and increased respiratory rate are characteristic findings in severe, life-threatening types of bacterial infection (e.g., septic shock, meningitis) and are likely the result of endotoxin release.

The signs and symptoms of meningitis in the very young and very old differ from those in older children and adults. In neonates, signs of meningeal irritation may be absent; fever, irritability, and poor feeding are often the only symptoms manifested.[23] Because S.C. is 5 years of age, accurate assessment of his mental status is challenging. Irritability (crying), as was manifested by S.C., is an important finding that suggests an altered mental status.

In elderly patients, many of the classic signs of meningeal irritation are absent as well, and the disease presentation can be subtler.[23] Therefore, given the grave consequences of a misdiagnosis, clinicians caring for infants and elderly patients must have a particularly high index of suspicion for meningitis.

Laboratory evaluation of meningitis should include serum chemistries and a hemogram as well as a detailed examination of the CSF.[23] The peripheral WBC count often is markedly elevated in acute bacterial meningitis, usually with a left shift evident on the differential. This finding, however, is nonspecific and occurs in many acute inflammatory and infectious diseases. S.C. has a marked leukocytosis with a predominance of PMN cells on the differential.

The abrupt onset of S.C.'s clinical symptoms is consistent with an acute bacterial process rather than a fungal or viral etiology. Given his age (5 years) and the community-acquired nature of the infection, the most likely pathogens for his meningitis are H. influenzae, N. meningitidis, and S. pneumoniae. The presence of maculopapular lesions argues for N. meningitidis as the causative pathogen because this is a common finding in cases of meningococcemia or meningococcal meningitis.[20] To make an accurate clinical and microbiologic diagnosis in S.C., it is necessary to obtain CSF for analysis. Thus, a lumbar puncture is required as soon as possible.

CEREBROSPINAL FLUID EXAMINATION

CASE 65-1, QUESTION 2: The resident in the ED performs a lumbar puncture, which yielded the following:

Opening pressure, 300 mm Hg (normal, <20)
CSF glucose, 20 mg/dL (normal, 50-60% of plasma glucose)
Protein, 250 mg/dL (normal, <50 mg/dL)
WBC count, 1,200 cells/μL, with 90% PMN, 4% monohistiocytes, and 6% lymphocytes
The CSF red blood cell (RBC) count was 50/μL. A stat Gram stain of CSF revealed numerous WBCs but no organisms. CSF, blood, and urine cultures are pending. Provide an assessment of the CSF results.

Careful examination of the CSF is essential to confirm the diagnosis of meningitis.[6] Table 65-3 compares the typical findings in CSF obtained from patients with acute bacterial meningitis with those seen with fungal or viral causes.[11,26,27] In acute bacterial meningitis, the CSF is often purulent, containing numerous WBCs with a predominance of PMNs, and often is turbid. CSF protein nearly always is elevated, and the CSF glucose concentration is low.[11] In contrast, CSF obtained in viral and fungal cases of meningitis usually is clear and characterized by a much lower WBC count with a mononuclear or lymphocyte predominance. Although the CSF protein concentration often is elevated, it may be normal. A variable effect is observed with CSF glucose.[11,26,27]

MICROBIOLOGIC EVALUATION

Microbiologic evaluation should include examination of CSF by Gram stain and culture as well as cultures obtained from other potential sites of infection (e.g., blood, sputum, urine). The presence of organisms on smear is indicative of a high bacterial inoculum (i.e., inoculum $>10^5$ colony-forming units/mL) and is associated with more fulminant disease.[22] The absence of organisms on Gram stain by no means rules out infection, but does make selection of empiric therapy more difficult. Although a positive Gram stain should prompt a re-evaluation of empiric therapy to ensure appropriate coverage, Gram stain results should not, by themselves, prompt a narrowing of appropriate empiric therapy.[8]

Table 65-3

Cerebrospinal Fluid (CSF) Findings in Various Types of Meningitis

Microbial Etiology	WBC Count (cells/μL)	Predominant Cell Type	Protein	Glucose
Bacterial	>500	PMN	Elevated	Low
Fungal	10–500	MN	Elevated	Variable
Viral	10–200	PMN or MN	Variable	Normal

MN, mononuclear cells; PMN, polymorphonuclear neutrophils; WBC, white blood cell.

S.C. has a negative Gram stain, which may be the result of previous antibiotic therapy or the early detection of disease. Given the negative CSF Gram stain result, S.C. must receive antibacterial therapy sufficiently broad to cover all pathogens associated with meningitis in his age group until the results from his CSF culture are available (usually within 24–48 hours). The CSF culture nearly always is positive in purulent meningitis, although CSF cultures can be negative in a patient who clearly has meningitis, particularly with antecedent receipt of antibiotic therapy.[6] Finally, results from cultures of other sites, such as the blood, urine, and sputum (when appropriate), can yield useful microbiologic information.

The CSF findings in S.C. also strongly support the diagnosis of bacterial meningitis. He has a markedly elevated opening CSF pressure, CSF leukocytosis (with a predominance of PMNs), an elevated CSF protein concentration, and a depressed CSF glucose value. A few RBCs are present in the CSF, which suggests contamination with peripheral blood caused by the traumatic nature of the lumbar puncture. Precise identification of the offending organism is not possible until CSF culture results are available.

Treatment Principles

Prompt institution of appropriate antimicrobial therapy is essential when treating meningitis. Delay in antibiotic administration is associated with increased morbidity and mortality.[8] When choosing antimicrobial therapy, a number of factors must be considered. First, the antibiotics selected must penetrate adequately into the CSF. In addition, the regimen chosen must have potent activity against known or suspected pathogens and exert a bactericidal effect.[28]

ANTIMICROBIAL PENETRATION INTO THE CEREBROSPINAL FLUID

The ability of antimicrobials to penetrate into CSF is affected by lipid solubility, degree of ionization, molecular weight, protein binding, and susceptibility to active transport systems operative within the choroid plexus. In general, the penetration of most antibiotics into the CSF is increased when the meninges are inflamed. Antimicrobial penetration into CSF is most commonly reported as a ratio of CSF to serum antimicrobial levels. Table 65-4 summarizes the CSF penetration characteristics of various antimicrobials during acute bacterial meningitis.[28],[29] Metronidazole, sulfamethoxazole, and trimethoprim are small, highly lipophilic compounds and penetrate into the CSF well, achieving adequate concentrations even when meningeal inflammation is absent. Rifampin is lipophilic but is a larger compound with a high degree of protein binding. Thus, it achieves satisfactory CSF penetration and may be combined with vancomycin to treat coagulase-negative staphylococcal infections in the CNS. Because β-lactams usually are ionized at physiologic pH, they are more polar and do not penetrate into the CSF as well. β-Lactams penetrate poorly when the meninges are intact, but when the meninges are inflamed, most penicillins and the third- and fourth-generation cephalosporins achieve CSF concentrations sufficient to treat meningitis (~10%–30% of simultaneously obtained serum concentrations). First- and second-generation cephalosporins are not recommended in the treatment of meningitis due to inadequate penetration and/or inferior efficacy.[30],[31] Ceftriaxone achieves sustained, reliable bactericidal activity within the CSF despite its high protein binding and has been used successfully to treat meningitis in both children and adults. An additional factor working against maintenance of therapeutic concentrations of β-lactams in the CSF is the active transport system of the choroid plexus, which pumps these organic acids out of the CSF. Meropenem achieves CSF levels 10% to 40% of serum levels.[28],[29] At the present time, data are too limited to draw conclusions on the utility of the newer agents ceftaroline, ceftolozane/tazobactam, or doripenem in the treatment of CNS infections.

Table 65-4

Cerebrospinal Fluid Penetration Characteristics of Various Antimicrobials

Very Good[a]
Commonly recommended: metronidazole (brain abscess), TMP-SMX (2nd line to ampicillin for empiric coverage of Listeria) Uncommonly utilized; reserve use for specific scenarios[b]: linezolid, rifampin, fluoroquinolones (ciprofloxacin, moxifloxacin, levofloxacin)
Good[c]
Penicillins: penicillin G, ampicillin, piperacillin, nafcillin
Other β-lactams: aztreonam, clavulanate, imipenem, meropenem, sulbactam, tazobactam
3rd- and 4th-generation cephalosporins[d]: cefotaxime, ceftazidime, ceftriaxone, cefepime
Other agents: vancomycin, doxycycline
Fair to Poor[e]
Aminoglycosides: amikacin, gentamicin, tobramycin Polymyxins: colistin, Polymyxin B
1st-generation cephalosporins: Cefazolin Other agents: macrolides (azithromycin, clarithromycin, erythromycin), clindamycin, daptomycin

[a] Generally achieve levels ≥20% of serum concentrations; generally penetrate CSF well regardless of meningeal inflammation.

[b] See text for details.

[c] Generally achieve levels 10% to 20% of serum concentrations; adequate CSF penetration achieved when the meninges are inflamed.

[d] Cefuroxime has similar CNS penetration, but is not recommended due to inferior efficacy.

[e] Penetration often inadequate even when the meninges are inflamed.

CSF, cerebrospinal fluid; TMP-SMX, trimethoprim–sulfamethoxazole.

The aminoglycosides have a low therapeutic index, and adequate CSF concentrations are difficult to achieve with IV dosing alone without risking significant toxicity. Thus, when aminoglycoside therapy is initiated for adults with CNS infections, concomitant intrathecal therapy is usually required. Similarly, the polymyxins are large hydrophilic compounds with substantial toxicity, and thus intrathecal administration is preferred.[28],[29]

Vancomycin is a large hydrophilic compound with moderate protein binding (50%) and as such does not diffuse well across the blood–CSF barrier. Therapeutic concentrations in the CSF (up to 30% of serum concentrations) may be attained with systemic vancomycin therapy when the meninges are inflamed. Other studies have found much lower penetration, however, and as such, concomitant intraventricular therapy also may be necessary in selected circumstances.[28],[29] Consensus guidelines recommend aggressive dosing (troughs 15–20 μg/mL) when treating meningitis.[32]

Fluoroquinolones are moderately lipophilic, have a molecular weight of ~300 Da, and are not protein bound to a large extent. As would be expected, they penetrate reasonably well into the CSF on a percentage basis (~40%–60% or higher).[28],[29] Despite this, clinical data supporting the use of fluoroquinolones for bacterial CNS infections are lacking, although some hypotheses may be made. First, given its potent activity against S. pneumoniae, moxifloxacin may be an option for pneumococcal infections with limited therapeutic options, such as infections caused by penicillin- and ceftriaxone-resistant isolates.[33] Second, CSF concentrations attained are likely inadequate for infection caused by bacteria with higher MICs (≥0.125–0.5 mcg/mL, depending on the specific organism and drug).[34] This is especially relevant because concerns regarding CNS toxicity have generally limited the study and practice of nonstandard, increased fluoroquinolone dosages for bacterial CNS infections.[28],[29] Finally, given the high rates of gram-negative resistance to fluoroquinolones, these agents should not be considered reliable as empiric therapy options in patients considered at risk for infections caused by such organisms.[35] Taken together, the fluoroquinolones are rarely utilized for the treatment of bacterial CNS infections.

Macrolides such as erythromycin and clarithromycin have a relatively high molecular weight and are substrates for a transporter that is abundant at the blood–brain barrier, P-glycoprotein. As such, they do not reach adequate concentrations when meningeal inflammation is lacking, and their lack of bactericidal activity further limits their utility in the treatment of bacterial meningitis. Bacteriostatic activity against S. pneumoniae also limits the utility of the tetracyclines and tigecycline. Clindamycin penetrates the CSF poorly and should not be used in the treatment of meningitis. Linezolid is also generally bacteriostatic, but as it often retains activity against multiresistant gram-positive pathogens and achieves CSF levels comparable to those in plasma, it may be considered an option for infections caused by gram-positive infections that are resistant or refractory to frontline options. Daptomycin is generally bactericidal and active against multiresistant gram-positive pathogens, but it is a large, highly protein-bound compound, and thus, CSF penetration is low (≤10% of plasma levels). Use of higher doses and intrathecal administration are being actively explored, but current utility is limited.[28],[29]

EMPIRIC THERAPY FOR CHILDHOOD MENINGITIS

CASE 65-1, QUESTION 3: A detailed medication and vaccination history reveals that S.C. and his brother appropriately received vaccination for Hib when they were 2 months of age. What constitutes appropriate empiric therapy for childhood meningitis? Which antibiotic would be appropriate for S.C.? What dose and route of administration should be used?

Because results from culture and sensitivity testing of CSF will not be available for >24 hours, empiric therapy must be instituted promptly. The regimen should take into consideration the patient's age, any predisposing conditions, results from the CSF Gram stain, history of allergy, and the presence of organ dysfunction. Table 65-5 gives recommendations for empiric antimicrobial therapy for acute bacterial meningitis.[11],[36]

S.C. is 5 years of age and has a negative CSF Gram stain. Therefore, therapy with a third-generation cephalosporin, such as ceftriaxone or cefotaxime, is preferred. Either of these two agents will provide excellent coverage of the most likely pathogens in this age group (S. pneumoniae and N. meningitidis).[11],[36] Of these two pathogens, S.C.'s rash suggests that N. meningitidis is likely.[37] H. influenzae is not very likely because he was vaccinated against Hib. Thus, initiation of ceftriaxone plus vancomycin would be appropriate for S.C. at this time.

Table 65-5

Empiric Therapy for Bacterial Meningitis

Age Group or Predisposing Condition	Recommended Therapy	Alternative Therapy
Neonates (<1 month)	Ampicillin + cefotaxime	Ampicillin + gentamicin
Infants and children (1–23 months)	Cefotaxime or ceftriaxone + vancomycin	Vancomycin + aztreonam/meropenem
Older children and adults (2–50 years)	Cefotaxime or ceftriaxone + vancomycin	Vancomycin + aztreonam/meropenem
Elderly (>50 years)	Ampicillin, cefotaxime, or ceftriaxone + vancomycin	Vancomycin + TMP-SMX + aztreonam or vancomycin + meropenem

Postneurosurgical	Vancomycin + ceftazidime/cefepime	Vancomycin + meropenem
Closed head trauma	Cefotaxime or ceftriaxone + vancomycin	Vancomycin + aztreonam/meropenem
Penetrating head trauma	Vancomycin + ceftazidime/cefepime	Vancomycin + meropenem
Immunocompromised	Vancomycin + cefepime + ampicillin	Vancomycin + TMP-SMX + aztreonam or vancomycin + meropenem

Use of a cephalosporin in this case is appropriate despite the allergic history with amoxicillin (history of skin rash). Patients with a documented penicillin allergy carry a 5% to 11% risk of cross-reactivity when cephalosporins are prescribed, depending upon the agent. In this setting, the type of reaction to penicillin is important to consider. Patients with a history of accelerated hypersensitivity reactions (e.g., hives, shortness of breath [SOB], or anaphylaxis) to penicillins should not be given cephalosporins in most instances. Conversely, a benign skin rash would not contraindicate use of a cephalosporin.[38] If S.C. had experienced an accelerated reaction to penicillin, vancomycin plus aztreonam, or meropenem would be the best alternative choice (Table 65-5).[11]

DOSING CONSIDERATIONS

In general, therapy of meningitis requires the use of high dosages of antimicrobials administered by the IV route. Table 65-6 lists the recommended dosing regimens for the treatment of CNS infections. S.C. should receive ceftriaxone in a dosage of 100 mg/kg/day given in one or two doses. A ceftriaxone regimen of 1,000 mg IV Q 12 hours is reasonable for S.C.

ADJUNCTIVE CORTICOSTEROID THERAPY

CASE 65-1, QUESTION 4: What is the rationale for adjunctive corticosteroid therapy in acute bacterial meningitis, and would it be appropriate for S.C.? How should dexamethasone be dosed and monitored for S.C.?

Corticosteroids, particularly dexamethasone, can reduce cerebral edema and lower intracranial pressure.[39] In addition, corticosteroids reduce the synthesis and release of the proinflammatory cytokines TNF-α and IL-1β from monocytes and astrocytes. These two cytokines play a central role in initiating the cascade of events that lead to neuronal tissue damage and neurologic sequelae.[40] Theoretically, then, inhibition of cytokine synthesis by corticosteroids in meningitis should lead to a decreased risk of hearing loss and other neurologic sequelae. Indeed, a prospective, randomized, double-blind multicenter trial evaluating the use of dexamethasone in adults with acute bacterial meningitis supported this theory.[41] A total of 301 patients were randomized to receive dexamethasone or placebo 15 to 20 minutes before or with the first dose of antibiotic every 6 hours for 4 days. Dexamethasone reduced the risk of unfavorable outcome, defined as a Glasgow Coma Scale score of 1 to 4 at 8 weeks (relative risk, 0.59; P = 0.03), and of death (relative risk, 0.48; P = 0.04). When the outcomes were analyzed based upon culture results, mortality reduction (14 vs. 34 percent) and all unfavorable outcomes (26 vs. 52 percent) were only seen with dexamethasone therapy in patients with meningitis caused by Streptococcus pneumoniae. Outcomes in patients with meningitis caused by organisms other than S. pneumoniae were independent of whether they received dexamethasone or not. Neither GI bleeding nor other adverse effects were increased in the dexamethasone group.

In children, several studies have also evaluated the role of adjunctive dexamethasone therapy in bacterial meningitis. Some prospective placebo-controlled, randomized trials have demonstrated that adjunctive dexamethasone therapy significantly reduces audiologic and neurologic sequelae in children >2 months of age. H. influenzae, however, was the causative pathogen in most of these meningitis cases, whereas the number of children with streptococcal and meningococcal meningitis in these trials was small.[2],[42–46] As previously mentioned, the number of Hib cases has decreased dramatically, making the data from these trials difficult to apply to the present day. More recently, of the 166 patients enrolled in a trial comparing dexamethasone to placebo, 35 and 26 cases were caused by S. pneumoniae and N. meningitides, respectively, in the treatment arm. Fewer audiologic and neurologic sequelae were observed in the dexamethasone-treated group compared with the placebo group, but the difference did not reach statistical significance.[47]

Most recently, a 2013 Cochrane meta-analysis evaluated data from 25 randomized trials that included over 4,000 children and adults. In the overall population, glucocorticoid administration did not significantly reduce mortality. However, glucocorticoids did reduce mortality in the subgroup of patients with meningitis caused by S. pneumoniae (RR, 0.84; 95% CI, 0.72–0.98). In studies conducted in high-income countries, glucocorticoids reduced severe hearing loss (RR, 0.51; 95% CI, 0.35–0.73), any hearing loss (RR, 0.58; 95% CI, 0.45–0.73), and short-term neurologic sequelae (RR, 0.64; 95% CI, 0.48–0.85). In the subgroup of over 2,000 children, the administration of dexamethasone did not affect mortality but did reduce the incidence of severe hearing loss, particularly in those with H. influenzae meningitis.[48]

The 2004 IDSA meningitis guidelines recommend that dexamethasone be initiated prior to (or concomitant with the first dose of) antimicrobial therapy in all adult patients with suspected or proven pneumococcal meningitis.[11] Controversy remains over whether dexamethasone should be continued in adults if the causative agent is found not to be pneumococcus because the number of patients in the studies with meningitis caused by other organisms was small.[49] However, the guidelines do recommend discontinuing dexamethasone if the organism is found to be something other than S. pneumonia.[11] Regarding pediatrics, the American Academy of Pediatrics (AAP) Committee on Infectious Diseases suggests that dexamethasone therapy may be beneficial in children with Hib meningitis if given before or at the same time as the first dose of antimicrobial therapy.[50] The AAP Committee on Infectious Diseases also suggests that the decision to use adjunctive dexamethasone therapy should be individualized but considered for infants and children older than 6 weeks with pneumococcal meningitis.[51] At this time, there can be no firm recommendation as to whether steroids should be continued in children if the pathogen is found not to be H. influenzae or S. pneumoniae.

Table 65-6

Suggested Antibiotic Dosing Regimens for Treatment of Central Nervous System Infections

	Daily Dose (interval in hours)[a]			
	Neonates			
Antibiotic	**0–7 days old**	**8–28 days old**	**Infants and Children**	**Adults**
Ampicillin	150 mg/kg (8)	200 mg/kg (6–8)	300 mg/kg (6)	12 g (4)
Aztreonam				8 g (6)
Nafcillin	75 mg/kg (8–12)	100–150 mg/kg (6–8)	200 mg/kg (6)	12 g (4)
Penicillin G	0.15 mU/kg (8–12)	0.2 mU/kg (6–8)	0.3 mU/kg (4–6)	24 mU (4)
Meropenem			120 mg/kg (8)	6 g (8)
Cephalosporins				
Cefotaxime	100–150 mg/kg (8–12)	150–200 mg/kg (6–8)	225–300 mg/kg (6–8)	12 g (4)
Ceftriaxone			80–100 mg/kg (12–24)	4 g (12)
Ceftazidime	100–150 mg/kg (8–12)	150 mg/kg (8)	150 mg/kg (8)	6 g (8)
Cefepime			150 mg/kg (8)	6 g (8)
Aminoglycoside[b,c]				
Gentamicin	5 mg/kg (12)	7.5 mg/kg (8)	7.5 mg/kg (8)	5–7 mg/kg (8–24)
Tobramycin	5 mg/kg (12)	7.5 mg/kg (8)	7.5 mg/kg (8)	5–7 mg/kg (8–24)
Amikacin	15–20 mg/kg (12)	30 mg/kg (8)	20–30 mg/kg (8)	15 mg/kg (8–24)
Others				
Moxifloxacin				400 mg (24)
Linezolid				1,200 mg (12)
Rifampin		10–20 mg/kg (12)	10–20 mg/kg (12-24)	600 mg (24)

TMP-SMX[d]			10–20 mg/kg (6–12)	10–20 mg/kg (6–12)
Vancomycin[c,e]	20–30 mg/kg (8–12)	30–45 mg/kg (6–8)	60 mg/kg (6)	30–45 mg/kg (8–12)

[a] Recommended daily dose when renal and hepatic functions are normal.

[b] Concurrent intraventricular doses of 5–10 mg (gentamicin, tobramycin) or 20 mg (amikacin) often required when treating gram-negative bacillary meningitis.

[c] Dose should be individualized based on serum level monitoring.

[d] Dose is based on the trimethoprim component.

[e] Concurrent intraventricular doses of 5–20 mg recommended if response to IV therapy is inadequate.

Source: Tunkel AR et al. Practice guidelines for the management of bacterial meningitis. Clin Infect Dis. 2004;39:1267.

Thus, S.C. should receive dexamethasone therapy, 0.15 mg/kg/dose given IV Q 6 hours for 2 to 4 days. For S.C., who is 20 kg, this would be 3 mg Q 6 hours, with the first dexamethasone dose given 15 minutes before initiating ceftriaxone therapy.

Potential adverse effects associated with dexamethasone include GI bleeding, mental status changes (e.g., euphoria or encephalopathy), increases in blood glucose, and possibly elevations in blood pressure. For S.C., the complete blood count (CBC), serum chemistries, and stool guaiac should be monitored daily while he is receiving dexamethasone. He also should be questioned about possible GI upset and assessed for changes in mental status (e.g., confusion, combativeness). Given the short duration of corticosteroid therapy, dexamethasone can be discontinued abruptly without tapering.

EFFECT ON CENTRAL NERVOUS SYSTEM PENETRATION OF ANTIBIOTICS

Another important issue to consider is whether dexamethasone, a potent anti-inflammatory agent, reduces the ability of antimicrobials to penetrate across the blood–brain barrier into CSF. Because CSF penetration of the penicillins, cephalosporins, and vancomycin is greatest when the meninges are inflamed, a hypothetical concern is that concomitant dexamethasone may reduce CSF concentrations of these agents, resulting in reduced efficacy. Early animal models suggest that vancomycin penetration into the CSF is reduced in dexamethasone-treated animals compared with animals not treated with steroids.[52] In a rabbit meningitis model, the coadministration of dexamethasone and vancomycin resulted in 29% less penetration of vancomycin into the CSF. By increasing the daily dose of vancomycin in these rabbits, however, therapeutic CSF levels were achieved, suggesting that giving larger daily doses of vancomycin circumvents the steroid effect on CNS penetration.[53] Additionally, current human data suggest that CSF penetration of vancomycin or ceftriaxone is not diminished with concomitant administration of dexamethasone.[54–57] Based on these encouraging findings, it is recommended that dexamethasone be utilized in all patients.[11]

Neisseria meningitidis Meningitis

DEFINITIVE THERAPY

CASE 65-1, QUESTION 5: Twenty-four hours after admission, S.C.'s culture results from his blood and CSF samples are available. The CSF culture is growing N. meningitidis (penicillin MIC, 0.06 mg/L), and N. meningitidis is also growing in both of the two collected blood cultures. What modification in S.C.'s antimicrobial therapy is necessary at this time?

Once culture and sensitivity results become available, definitive therapy can be instituted, often with a single agent (Table 65-7).[11],[36] As suspected, S.C.'s CSF culture is positive for N. meningitidis. Cefuroxime, a second-generation cephalosporin, has activity against N. meningitides; however, it is less effective for meningitis than third-generation cephalosporins and should not be used.[58],[59] The reason for the inferiority of cefuroxime relative to ceftriaxone most likely is related to reduced potency.[58]

Because N. meningitidis is susceptible to penicillin and ampicillin currently, penicillin is the drug of choice. However, S.C.'s questionable history of amoxicillin rash makes the use of ceftriaxone a reasonable choice (See Table 65-6 for dosing).

MONITORING THERAPY

CASE 65-1, QUESTION 6: What subjective and objective data should be monitored to evaluate the efficacy and toxicity of treatment of patients with meningitis, and what specifically should be monitored in S.C.?

Clinical signs and symptoms attributable to the disease, such as fever, altered mental status, and stiff neck, should be checked periodically throughout the day and monitored for resolution. S.C.'s temperature and mental status should be assessed often. Accurate assessment of S.C.'s mental status can be difficult because of his young age. Thus, his baseline level of mental status should be evaluated (e.g., whether he is awake and alert, or lethargic and difficult to arouse). If awake and alert, S.C. should be observed for irritability, because this often is the only sign of altered mentation. Questions can be used to assess his orientation: Does he know where he is? Does he know his name? Can he recognize his mother or other family members? In general, signs of clinical improvement should be evident within 24 to 48 hours for most uncomplicated cases of acute bacterial meningitis, with defervescence of fever achieved in a mean of 3.3 days in one trial of cefotaxime in children.[60]

Laboratory tests should be monitored as well. A CBC with differential, serum electrolytes (e.g., Na, K, Cl, HCO_3), blood glucose, and renal function tests (e.g., BUN, SrCr) should be performed daily. Abnormal electrolyte results may require more frequent monitoring. Laboratory abnormalities, such as leukocytosis and hyponatremia, may take longer to normalize than clinical symptoms. CSF chemistries usually improve within 48 hours of starting therapy, although CSF WBC and protein may remain elevated for a week or more.[61],[62] With effective therapy, the CSF culture usually is sterile after about 18 to 24 hours of therapy.[58],[60] Delays in CSF sterilization are associated with a higher propensity for neurologic complications.[58] If S.C. responds to therapy in a straightforward manner, he need not to have a repeat lumbar puncture. If the response is inadequate, as evidenced by persistent fever or deteriorating mental status, S.C. will require a repeat lumbar puncture to re-examine the CSF parameters.[11]

Table 65-7

Definitive Therapy for Bacterial Meningitis

Pathogen	**Recommended Treatment**	**Alternative Agents**
Haemophilus influenzae		
β-Lactamase negative	Ampicillin	Cefotaxime or ceftriaxone; aztreonam
β-Lactamase positive	Cefotaxime or ceftriaxone	Aztreonam
Neisseria meningitidis	Penicillin MIC < 0.1 mcg/mL: penicillin G or ampicillin	Cefotaxime or ceftriaxone; meropenem
	Penicillin MIC 0.1- 1.0 mcg/mL: cefotaxime or ceftriaxone	
Streptococcus pneumoniae	Penicillin MIC ≤ 0.06 mcg/mL: penicillin G or ampicillin	Cefotaxime or ceftriaxone
	Penicillin MIC ≥ 0.12 mcg/mL: cefotaxime or ceftriaxone if susceptible	Vancomycin or meropenem
	Penicillin and cefotaxime/ceftriaxone nonsusceptible: vancomycin + cefotaxime/ceftriaxone ± rifampin	Vancomycin + moxifloxacin
Streptococcus agalactiae	Penicillin G or ampicillin + gentamicin	Cefotaxime or ceftriaxone
Listeria monocytogenes	Penicillin G or ampicillin ± gentamicin	TMP-SMX or meropenem
Enterobacteriaceae[a]		
Escherichia coli, Klebsiella species	Cefotaxime or ceftriaxone	Cefepime; aztreonam; meropenem
Enterobacter, Serratia species	Cefepime; meropenem	TMP-SMX; aztreonam
Pseudomonas aeruginosa	Cefepime or ceftazidime; meropenem	Aztreonam
Staphylococcus aureus[a]		
Methicillin-susceptible (MSSA)	Nafcillin or oxacillin	Vancomycin ± rifampin;

		meropenem
Methicillin-resistant (MRSA)	Vancomycin± rifampin	TMP-SMX; linezolid
Staphylococcus epidermidis[a]	Vancomycin ± rifampin	TMP-SMX; linezolid

[a]Concomitant intrathecal therapy may be required for optimal response (most commonly an intrathecal aminoglycoside for gram-negative or intrathecal vancomycin for gram-positive infections).

MIC, minimum inhibitory concentration; TMP-SMX, trimethoprim–sulfamethoxazole.

In addition to monitoring the therapeutic response, side effects of the antimicrobial regimen also need to be assessed frequently. Meningitis requires high-dose therapy, making the likelihood of adverse effects much greater. Currently, S.C. is being treated with ceftriaxone. The adverse effects most often associated with ceftriaxone include hypersensitivity reactions, mild pain and phlebitis at the injection site, and GI complaints.[63] S.C. should be observed for the formation of an antibiotic-related skin rash or evidence of an accelerated allergic reaction (e.g., hives, wheezing). The IV catheter site should be observed daily for redness, tenderness, or pain on palpation of the vein. S.C. should be watched closely for loose stools or diarrhea. Although mild diarrhea is a common side effect of most antimicrobials that rarely requires a change in therapy, diarrhea that is severe, persistent, or accompanied by fever, unexplained leukocytosis, or abdominal cramping should prompt testing for C. difficile colitis.[59],[64]

CEFTRIAXONE-INDUCED BILIARY PSEUDOLITHIASIS

CASE 65-1, QUESTION 7: After 5 days of treatment, the nurse caring for S.C. notes that his appetite is markedly diminished, and he complains of an upset stomach. S.C. was afebrile and alert and oriented, but abdominal examination revealed "guarding," with pain localized in the right upper quadrant area. Laboratory data at this time are as follows:

WBC count, 6,000 cells/μL
Hgb, 12.5 g/dL
Hct, 34%
Platelets, 120,000/μL
Na, 135 mEq/L
K, 3.6 mEq/L
Cl, 98 mEq/L
Aspartate aminotransferase (AST), 35 units/L
Alanine aminotransferase (ALT), 33 units/L
Alkaline phosphatase, 110 MU/dL
Total bilirubin, 1.2 mg/dL
Amylase 70 units/L

A stool guaiac is negative. What are possible causes of S.C.'s abdominal discomfort?

A number of possible causes exist for S.C.'s abdominal discomfort. His corticosteroid therapy may have caused acute GI bleeding; however, the dexamethasone was discontinued 3 days ago and S.C.'s hemoglobin and hematocrit values are in the low-normal range. The negative stool guaiac result also argues strongly against a GI bleed. Acute pancreatitis is unlikely given the normal amylase result. Viral or drug-induced hepatitis is another possibility but also is unlikely given his normal AST, ALT, and bilirubin results. An intra-abdominal infection also is possible, but this is improbable because he is afebrile and has a normal WBC count. Other causes, such as acute cholecystitis or appendicitis, require further diagnostic evaluation.

CASE 65-1, QUESTION 8: An abdominal ultrasound reveals sludge in the gallbladder. What is the significance of this finding in S.C., and how should this abnormality be managed?

The abnormality on S.C.'s abdominal ultrasound explains his right upper quadrant pain. S.C. has what appears to be a condition known as biliary pseudolithiasis (i.e., biliary "sludging"). Biliary sludging can occur in conditions of gallbladder hypomotility (e.g., recent surgery, burns, total parenteral nutrition) and, in some instances, can be drug-induced. S.C. has been receiving ceftriaxone for treatment of his meningitis, and this drug can cause biliary pseudolithiasis.[65]

Antibiotic-associated biliary pseudolithiasis is seen almost exclusively with ceftriaxone. The biliary excretion associated with ceftriaxone results in very high concentrations of the drug in gallbladder bile. In selected circumstances, the biliary concentration of ceftriaxone may exceed solubility limits, resulting in formation of a fine, granular precipitate (i.e., sludge), which differs in composition and ultrasound features from true gallstones. The precipitate is composed of a ceftriaxone–calcium complex, the formation of which is dose dependent. Given the high dosages required for meningitis therapy, it is not surprising that this adverse effect has occurred in S.C.[65] In the comparative randomized trial between ceftriaxone and cefuroxime cited previously, evidence of biliary pseudolithiasis on abdominal ultrasonography was observed in 16 of 35 (46%) patients who received ceftriaxone and in none of 35 patients receiving cefuroxime.[58] Pseudolithiasis usually appears 3 to 10 days following the start of therapy and, in most instances, it is clinically asymptomatic. Symptoms similar to acute cholecystitis are evident in some individuals and include nausea with or without vomiting and abdominal right upper quadrant pain.[65]

Prompt recognition of this adverse effect and discontinuation of ceftriaxone therapy are required to effectively manage biliary pseudolithiasis. Once S.C.'s ceftriaxone is discontinued, the condition should resolve gradually over a period of weeks to months; the clinical symptoms should disappear within a few days.[65] Cefotaxime can be substituted for ceftriaxone; cefotaxime is not associated with biliary complications, and the efficacy of these two agents is equivalent.[63] For S.C., the cefotaxime dosage would be 1,000 mg IV every 6 hours (Table 65-6).

DURATION OF THERAPY

CASE 65-1, QUESTION 9: What is the recommended duration of antimicrobial therapy for S.C.?

The optimal duration of therapy for meningitis is difficult to ascertain because few trials have been designed to address this issue.[66] Although general guidelines exist, the duration should be individualized based on the response to therapy, the presence of complicating factors (e.g., immunosuppression), and the specific causative pathogen. Table 65-8 lists the recommended treatment durations for uncomplicated cases of bacterial meningitis according to the specific pathogen. Patients such as S.C. with meningitis caused by N. meningitidis should be treated for 7 days.[11] Complicated cases, such as those with delayed CSF sterilization, require therapy for longer periods (up to 2 weeks or more).

Table 65-8

Duration of Therapy for Bacterial Meningitis

Etiology	Duration of Therapy (days)
Haemophilus influenzae	7
N. meningitidis	7
Streptococcus pneumoniae	10–14
Group B streptococci (Streptococcus agalactiae)	14–21
Listeria monocytogenes	≥21
Gram-negative bacilli	21

PREVENTION OF NEISSERIA MENINGITIDIS MENINGITIS

CASE 65-1, QUESTION 10: S.C. is ready to be discharged home. How can the potential spread of meningococcal disease be prevented in persons with whom S.C. has contact?

Despite an excellent response to therapy, S.C. still may harbor N. meningitidis in his nasopharynx and could transmit this organism to individuals with whom he has close contact.[18],[67],[68] Therefore, chemoprophylaxis to prevent secondary cases of N. meningitidis is indicated for S.C. and his close contacts. In this context, close contacts include the following: a household member including roommates and young adults in dormitories, child-care center contacts, and any person directly exposed to the patient's oral secretions (e.g., through kissing, mouth-to-mouth resuscitation, or endotracheal intubation) in the 7 days before symptom onset and until 24 hours after initiation of appropriate antibiotics.[67],[69] Health-care personnel and any passenger on a flight who had direct contact with respiratory secretions or for anyone seated directly next to an index patient on a prolonged flight (e.g., one lasting ≥8 hours) should also receive chemoprophylaxis.[69]

S.C.'s 7-year-old brother, the children at the day-care center, and close contacts at the hospital who have been caring for S.C. are at risk for invasive N. meningitidis disease and should receive chemoprophylaxis. Because the risk of secondary disease is greatest immediately after onset of disease in the index patient, chemoprophylaxis should be instituted as soon as possible and ideally within 24 hours.[67] Administering chemoprophylaxis 14 days or more after identification of the index case is of little value. Regimens to reduce nasopharyngeal carriage of N. meningitidis include rifampin, ciprofloxacin, and ceftriaxone. The most frequently used regimen for children ≥1 month is rifampin, given every 12 hours in a dosage of 10 mg/kg/dose for 2 days. For adults, rifampin given every 12 hours in a dosage of 600 mg for 2 days is commonly used. The index patient should also receive prophylaxis if he/she was treated with an agent other than a third-generation cephalosporin as soon as he/she is able to tolerate oral medications and prior to being discharged from the hospital.[69]

Because S.C. is receiving ceftriaxone, he does not need chemoprophylaxis. S.C.'s brother, parents, and day-care contacts should be treated with appropriate doses of rifampin as soon as he is diagnosed. Because rifampin is not recommended for pregnant women, ceftriaxone would be a viable alternative.

Streptococcus pneumoniae Meningitis

CLINICAL FEATURES, PREDISPOSING FACTORS, AND DIAGNOSIS

CASE 65-2

QUESTION 1: A.L., a 58-year-old man with a long history of alcohol abuse, is admitted to the ED febrile and unresponsive. During the past several days, A.L. has experienced intermittent episodes of fever, chills, SOB, and a worsening productive cough. A friend visiting A.L. called 9-1-1 when he could not arouse him. A.L.'s medical records indicate that he has hypertension, adult-onset diabetes mellitus, peptic ulcer disease (PUD), and chronic obstructive pulmonary disease (COPD). A splenectomy was performed 10 years ago after trauma to the abdomen. A.L. is divorced and lives alone in a low-income apartment. He has no known drug allergies. His records show him to be a smoker for more than 30 years. Current medications include hydrochlorothiazide 50 mg every other day, glipizide 5 mg orally (PO) twice daily, famotidine 20 mg PO every bedtime, and doxycycline PO twice daily as needed for cough and increased sputum production.

On admission to the ED, A.L. had a temperature of 40°C, blood pressure of 90/50 mm Hg, and pulse and respiratory rates of 115 beats/minute and 25 breaths/minute, respectively. His weight is 59 kg. A.L. was unresponsive but withdrew all extremities to painful stimuli. His pupils were equal and sluggishly reactive to light; papilledema and evidence of meningismus were present. Wheezes and crackles were heard throughout both lung fields, with dense consolidation noted in the left lower lobe. The remainder of his physical examination was noncontributory.

Stat laboratory tests revealed the following:

WBC count, 18,000 cells/μL, with 80% PMN, 15% bands, 3% lymphocytes, and 2% basophils
Hgb, 10.5 g/dL
Hct, 34%
Platelet count, 250,000/μL
K, 3.0 mEq/L
Glucose, 250 mg/dL
AST, 190 mg/dL

ALT, 140 mg/dL
BUN, 35 mg/dL
SCr, 2.4 mg/dL

The prothrombin time was high normal, and albumin was 3.1 mg/dL. A stat blood alcohol level of 100 mg/dL was reported, and a urine toxicology screen was negative. A.L.'s serum theophylline concentration was 18 mg/dL. Stool guaiac was positive.

A CT scan showed no evidence of mass lesions or cerebral hematoma. Lumbar puncture yielded the following results:

CSF opening pressure, 200 mm Hg
Protein, 120 mg/dL
Glucose, 100 mg/dL
WBC count, 8,500 cells/µL, with 92% PMN, 4% monohistiocytes, and 4% lymphocytes
RBC count, 400/µL

Gram-positive, lancet-shaped diplococci were visible on CSF Gram stain. In addition, a sputum Gram stain revealed numerous WBCs, few epithelial cells, and numerous gram-positive cocci in pairs and in short chains. Blood, CSF, urine, and sputum cultures are pending. What are the clinical and laboratory features of pneumococcal meningitis? What features of pneumococcal meningitis are present in A.L.?

A.L. presents to the ED with many signs and symptoms suggestive of pneumococcal meningitis. He is 56 years of age, and S. pneumoniae is the most common bacterial etiology for meningitis in adults >30 years of age (Table 65-1). As is evidenced by A.L.'s presentation, invasive pneumococcal disease often is associated with significant morbidity, and mortality rates remain high.[1] However, likely due to the introduction of conjugate vaccines, the incidence of S. pneumoniae meningitis in the United States has significantly decreased, from 0.8 cases per 100,000 people in 1997 to 0.3/100,000 in 2010.[70] Predisposing factors to invasive pneumococcal disease include advanced age, cigarette smoking, alcoholism, diabetes, chronic pulmonary disease, and functional (sickle cell disease) or anatomic (splenectomy) asplenia. In addition, individuals infected with the human immunodeficiency virus (HIV) or with other immunocompromising conditions (such as solid organ or bone marrow transplantation) are at higher risk. Patients with CSF otorrhea or rhinorrhea induced by closed head trauma or neurosurgical procedures are more susceptible to develop pneumococcal meningitis as well.[71]

A.L. has many predisposing factors for pneumococcal meningitis. He smokes, has a long history of alcohol abuse, has had a splenectomy, and has diabetes and COPD. A diagnosis of

---

pneumococcal meningitis in A.L. is supported by the high fever, stiff neck (meningismus), and altered mental status. He is unresponsive, which is a definite negative prognostic factor.[72] Results from CSF chemistries and microbiologic analysis are highly suggestive of pneumococcal meningitis. A.L. has an elevated opening CSF pressure and a markedly elevated CSF protein and WBC count with a predominance of neutrophils on differential examination. The normal CSF glucose level (100 g/dL) is misleading because A.L. is diabetic. The calculated ratio of CSF to serum glucose for A.L. is <50%, which is consistent with acute bacterial meningitis (Table 65-3). The presence of gram-positive, lancet-shaped diplococci in pairs on the CSF Gram stain strongly supports the diagnosis of pneumococcal disease. The signs and symptoms of pneumococcal pneumonia (cough, SOB, increased sputum production, and pulmonary consolidation) as well as the sputum Gram stain result also lend support to a diagnosis of invasive pneumococcal infection.

EMPIRIC THERAPY IN ADULTS

CASE 65-2, QUESTION 2: What would be appropriate therapy for A.L?

Table 65-7 provides therapy recommendations for pneumococcal meningitis based on penicillin and ceftriaxone/cefotaxime susceptibility. Resistance among pneumococci to penicillin G (MIC ≥0.12 mcg/mL) is a significant concern. In a surveillance study from 2006 to 2007, 27.5% of S. pneumoniae isolates from patients with meningitis were resistant to penicillin.[73] S. pneumoniae strains in CSF with MIC >0.5 mcg/mL to cefotaxime or ceftriaxone are intermediate (1 mcg/mL) or resistant (≥2 mcg/mL). Reduced activity of ceftriaxone and cefotaxime against penicillin-resistant pneumococci affects the therapeutic ratio achieved in CSF and has been associated with clinical failure. Optimal therapy for fully penicillin-resistant pneumococcal meningitis should include vancomycin. The combination of vancomycin and ceftriaxone was superior to either agent given alone in a rabbit model of penicillin-resistant pneumococcal meningitis. Ceftriaxone or vancomycin combined with rifampin also may be superior to either drug given alone.[74] With its potent pneumococcal activity and satisfactory CNS penetration, moxifloxacin may be an option for pneumococcal meningitis caused by penicillin- and ceftriaxone-resistant isolates.[33] However, clinical data supporting the use of moxifloxacin in this scenario are lacking. Thus, until more information is available, the combination of ceftriaxone or cefotaxime with vancomycin represents the most reasonable approach to empiric therapy for potential penicillin-resistant pneumococcal meningitis.

Until culture and susceptibility results are available, the recommended antibiotic in this situation is ceftriaxone 2 g given IV Q 12 hours and vancomycin 30 to 45 mg/kg/day IV divided Q 8 to 12 hours. A.L. weighs 59 kg, and because his renal function is not normal (SrCr, 2.4 mg/dL; creatinine clearance, 30 mL/minute), a dosage adjustment was made.

CORTICOSTEROID THERAPY FOR ADULT MENINGITIS

CASE 65-2, QUESTION 3: Should A.L. receive corticosteroid therapy in addition to his antibiotic therapy?

A.L. presents with profoundly altered mental status, and his signs and symptoms are consistent with a fulminant course of disease. His age, underlying medical problems, likely streptococcal meningitis, and deteriorating clinical status all point to a poor prognosis and argue for the use of adjunctive dexamethasone. On the other hand, A.L. is diabetic and has an elevated glucose concentration. He also has PUD, which may be active given that he is anemic and has a positive stool guaiac result. High-dose dexamethasone therapy may impact upon his mental status, making assessment even more difficult. Although each of these issues is a concern, none is so critical as to preclude the use of corticosteroids. Therefore, dexamethasone given in a dosage of 10 mg IV Q 6 hours could be instituted before starting ceftriaxone therapy provided that the diagnosis of bacterial meningitis is confirmed. Dexamethasone can be continued for up to 4 days if S. pneumoniae is found to be the causative pathogen. Dexamethasone may be discontinued if S. pneumoniae is not the causative pathogen.[11] To control blood glucose, a sliding-scale dosing schedule of regular insulin is recommended. A.L.'s PUD should be properly worked up and treated if necessary.

TREATMENT OF PENICILLIN-SUSCEPTIBLE PNEUMOCOCCAL MENINGITIS

CASE 65-2, QUESTION 4: Results from A.L.'s CSF, blood, and sputum cultures are available and are positive for S. pneumoniae at each site. Sensitivity testing in CSF revealed an MIC of 0.06 mcg/mL to penicillin, 0.25 mcg/mL to cefotaxime and ceftriaxone, and 0.25 mcg/mL to vancomycin. What therapy is indicated for A.L.?

A.L. is infected with a strain of S. pneumoniae that is susceptible to penicillin G (Table 65-7).[75] The dosage usually is 24 million units/day in adults with normal renal function (Table 65-6). A.L. has renal impairment, however, which means he should receive a reduced penicillin dosage. For A.L., who has a calculated creatinine clearance of ~28 mL/minute (according to the method of Cockcroft and Gault), the daily dose would be 12 to 16 million units, or 3 to 4 million units Q 6 hours. This revised regimen should provide penicillin serum concentrations similar to those achieved with high-dose therapy when kidney function is normal. Failure to adjust the dosage appropriately is equivalent to providing massive doses of penicillin, and seizures may result.[76] In patients unable to tolerate penicillin G, the best alternatives are ceftriaxone or cefotaxime (Table 65-7).[11,36]

Gram-Negative Bacillary Meningitis

CASE 65-3

QUESTION 1: R.R., a 40-year-old, 80-kg man, is admitted to the hospital for a cervical laminectomy with vertebral fusion. His surgical procedure was complicated by a dural tear. On the third postoperative day, drainage at his surgical excision site was noted, and R.R. was febrile to 38.2°C. A Gram stain of the drainage revealed few gram-positive cocci and moderate gram-negative bacilli. Therapy with IV cefazolin 1 g every 8 hours was begun. The following morning, R.R. was oriented to person, place, and time, but he was slightly obtunded and had a temperature of 40°C. Neck stiffness could not be assessed because of his recent surgery. A magnetic resonance imaging (MRI) scan of the head and neck was negative, and lumbar puncture yielded the following CSF results:

WBC count, 3,000 cells/μL, with 95% PMN
Glucose, 20 mg/dL
Protein, 280 mg/dL
What important clinical and laboratory features of gram-negative bacillary meningitis are manifested in R.R.?

EPIDEMIOLOGY

R.R. has developed gram-negative meningitis as a complication of his recent neurosurgical procedure. Gram-negative organisms are important pathogens particularly after neurosurgical

---

procedures such as craniotomy.[70] Historically, mortality rates from gram-negative bacillary meningitis have been extremely high, ranging from 40% to 70%. With the availability of third-generation cephalosporins, some studies report fatalities have declined to <40%; however, a recent study of 40 adults with spontaneous gram-negative meningitis reported a mortality rate of 53%.[77] Increasing resistance among certain gram-negative bacilli, such as Enterobacter species and P. aeruginosa, presents a therapeutic dilemma in that mortality associated with these pathogens is high and therapeutic options are fewer.

PREDISPOSING FACTORS

Individuals at greatest risk for gram-negative bacillary meningitis include neonates, the elderly, patients with underlying conditions such as diabetes mellitus or malignancy, patients with open trauma to the head, and individuals such as R.R. undergoing neurosurgical procedures.[78] Although meningitis is a rare complication of clean neurosurgical procedures (e.g., craniotomy, laminectomy), the consequences can be devastating when it does happen.[77]

MICROBIOLOGY

Escherichia coli and K. pneumoniae have historically been the most common gram-negative bacteria causing meningitis; however, rates of pseudomonal meningitis appear to be increasing.[77],[79] E. coli is the most common gram-negative cause of neonatal meningitis, whereas K. pneumoniae is isolated more often in the elderly population.[80],[81] The remaining cases are generally divided evenly among Proteus, Serratia, Enterobacter, Citrobacter, Pseudomonas, and other less common bacilli.[77]

CLINICAL FEATURES

In general, clinical laboratory features of gram-negative bacillary meningitis are similar to other types of bacterial meningitis.[1],[11] Because of high virulence, gram-negative bacillary meningitis often is a fulminant, rapidly progressive disease. An exception to this rule is meningitis after neurosurgery.[81] As is evidenced by R.R.'s clinical presentation, postneurosurgical gram-negative bacillary meningitis can present in a more subtle fashion. In such patients, many of the symptoms of meningitis (e.g., altered mental status, stiff neck) are masked by underlying neurologic disease. Thus, a high index of suspicion is warranted in the postsurgical setting. In addition to gram-negative bacilli, staphylococci also are associated with postneurosurgical meningitis.[82] The presence of what looks like staphylococci on R.R.'s wound drainage fluid is of concern, but the abundance of gram-negative rods on his CSF Gram stain supports the latter as being the most likely causative pathogen.

TREATMENT OF GRAM-NEGATIVE BACILLARY MENINGITIS

CASE 65-2, QUESTION 2: What empiric therapy is appropriate for A.L. at this time?

Fewer choices are available for treatment of gram-negative bacillary meningitis than for other meningitides. Ampicillin is active against only E. coli, P. mirabilis, and Salmonella species, but resistance has essentially eliminated its use. Aminoglycosides are limited by their inability to achieve therapeutic CSF concentrations, as well as reduced activity in the acidic milieu of purulent CSF.[83] Intraventricular administration, which results in therapeutic CSF concentrations, is usually reserved for difficult-to-eradicate shunt infections in combination with IV therapy because of the absence of data supporting their use.[21],[43] Unlike intraventricular administration, intralumbar injections will not result in therapeutic CSF concentrations in the ventricle.[43]

Empiric antimicrobial regimens should include an agent with activity against P. aeruginosa in patients with penetrating head trauma, a CSF shunt, or in patients who recently underwent a neurosurgical procedure. Because R.R. recently had a neurosurgical procedure, his empiric therapy should include an antipseudomonal agent such as cefepime, ceftazidime, or meropenem (Table 65-5).[11] Cefepime has excellent activity against E. coli and K. pneumoniae and is active against other enteric gram-negative bacilli as well (Table 65-7).[31] Resistance to third-generation cephalosporins among Enterobacter, Citrobacter, and Serratia is so prevalent that these agents cannot be relied on for the treatment of meningitis caused by these pathogens.[84] With this in mind, therapy of gram-negative meningitis in situations where third-generation cephalosporin resistance is likely (e.g., nosocomial or postneurosurgical meningitis) should result in the use of cefepime or meropenem. If a pathogen is isolated, therapy may be tailored based on culture results, antibiotic sensitivities, and antibiotic penetration into the CNS. For example, success rates exceed 80% with cefotaxime and ceftriaxone for gram-negative bacillary meningitis caused by E. coli or K. pneumoniae.[85],[86] For R.R., cefazolin should be discontinued, and treatment with cefepime adjusted for renal insufficiency (2 g IV Q 8 hours) should be instituted until the return of culture and sensitivities.

TREATMENT OF ENTEROBACTER MENINGITIS

CASE 65-3, QUESTION 3: Culture results from R.R.'s wound drainage and CSF both are positive for Enterobacter cloacae. Sensitivity data reveal resistance to ceftriaxone, cefepime, ceftazidime, piperacillin–tazobactam, and aztreonam. Drugs to which the isolate is sensitive include imipenem, meropenem, TMP-SMX, gentamicin, tobramycin, and ciprofloxacin. What alteration in antimicrobial therapy is most appropriate for R.R. at this time?

Treatment of meningitis caused by Enterobacter and related species (e.g., Serratia, Citrobacter species) presents a particular challenge.[31],[87] Furthermore, some isolates that are sensitive to third-generation cephalosporins can become resistant during therapy by virtue of selecting for derepressed mutants.[88] Thus, in contrast to gram-negative bacillary meningitis caused by E. coli and Klebsiella species, alternative therapies are needed when treating meningitis caused by Enterobacter, Serratia, Citrobacter, and Pseudomonas species. The isolate is sensitive to imipenem, but the higher propensity for seizures compared with other β-lactams (including penicillin G) argues against its use in R.R.[87] Meropenem is not considered to be epileptogenic and should be used preferentially to imipenem for meningitis.[89] Clinical trials have evaluated the efficacy and safety of meropenem versus cefotaxime in the treatment of meningitis in children. Clinical outcomes were similar among the patients randomized to either group, and the incidence of seizures was similar in the treatment groups.[90],[91] Thus, after consideration of the aforementioned options, meropenem appears to be the best choice of therapy for R.R and carries FDA (Food and Drug Administration) approval for this indication; however, TMP-SMX, although not FDA-approved, may be an option as well.[92] Cefepime should be discontinued and, if confirmed to be susceptible, therapy started with meropenem 2 g IV every 8 hours adjusted for renal insufficiency.

DURATION OF THERAPY

The optimal duration of therapy for gram-negative bacillary meningitis has not been clearly established. Because of the high mortality and morbidity associated with these pathogens and the reduced susceptibility of enteric pathogens to antimicrobial agents, 21 days has been suggested and should be provided for R.R. (Table 65-8).[11]

Staphylococcus epidermidis Meningitis or Ventriculitis

CLINICAL PRESENTATION OF CEREBROSPINAL FLUID SHUNT INFECTIONS

CASE 65-4

QUESTION 1: T.A., a 21-year-old woman with a history of congenital hydrocephalus, is admitted to the neurosurgery unit for worsening mental status and fever. T.A. has a history of multiple revisions and placements of intraventricular shunts for control of hydrocephalus. Currently, she has a ventriculoperitoneal (VP) shunt, which was placed 1 month ago and previously had been functioning normally. During the past few days, T.A. has exhibited worsening obtundation, stiff neck, and a temperature of 39.5°C. A CT scan performed today reveals enlarged ventricles consistent with acute hydrocephalus.

T.A.'s medical history is noncontributory except for a seizure disorder for which she takes phenytoin 400 mg PO at bedtime. She also takes Lo-Ovral for birth control. T.A. is allergic to sulfa drugs (severe skin rash). Her weight on admission is 60 kg.

Laboratory analysis was significant for the following:

WBC count, 14,000 cells/μL, with a differential of 85% PMNs and 10% lymphocytes
BUN, 19 mg/dL
SCr, 0.9 mg/dL

A tap of T.A.'s shunt was performed, and the ventricular fluid was notable for the following results:

Total protein, 150 mg/dL
Glucose, 40 mg/dL
WBC count, 200 cells/μL, with 85% PMNs and 10% lymphocytes

Gram stain of the ventricular fluid showed numerous gram-positive cocci in clusters. What are the subjective and objective findings of CSF shunt infections, and what manifestations of this type of infection are present in T.A.?

T.A. likely has meningitis with ventriculitis secondary to infection of her VP shunt. The most important way to manage hydrocephalus involves the use of devices that divert (shunt) CSF from the cerebral ventricles to other areas of the body such as the peritoneum (VP shunts) or atrium (ventriculoatrial shunts).[93] This approach alleviates increased CSF pressure and substantially reduces morbidity and mortality.[94] Infection of these devices, however, is a common cause of shunt malfunction, as seen in T.A. The reported incidence of CSF shunt infections in children is approximately 11% in recent studies and varies in adults from 2.5% to 15% depending on patient factors, surgical technique, and the type and duration of the procedure performed (i.e., shunt revision vs. placement of a new device).[95–97] T.A., who has been hydrocephalic since birth and has a history of multiple shunt procedures, is at high risk for such an infection.

Clinical symptoms associated with infected CSF shunts vary widely from asymptomatic colonization to fulminant ventriculitis with meningitis. Fever is common and, in many instances, is the only presenting symptom. CSF findings also are slightly different in shunt infection compared with acute meningitis: The WBC count usually is not as elevated, the decrease in CSF glucose is less pronounced, and the protein value may be normal or slightly elevated. CSF culture is positive in most patients.[98] T.A.'s clinical presentation, CSF findings, and radiographic evidence of hydrocephalus are highly suggestive of a VP shunt infection. She is febrile and has altered mental status. The presence of a stiff neck strongly suggests meningeal involvement. Evaluation of T.A.'s ventricular fluid reveals a slightly elevated WBC count, with a predominance of PMNs, an elevated protein concentration, and a slightly lower-than-normal glucose concentration.

Skin microflora are the most common causes for CSF shunt infections. Coagulase-negative staphylococci (usually S. epidermidis) account for roughly 50% of all cases and Staphylococcus aureus accounts for roughly one-fourth of all cases. Other less common pathogens include diphtheroids, enterococci, and Propionibacterium acnes. Enteric gram-negative bacilli are responsible for a small percentage of cases; these cases usually occur when the distal end of the shunt is inserted improperly into the peritoneal cavity.[98],[99] The gram-positive cocci in clusters on Gram stain of T.A.'s CSF strongly suggest a staphylococcal shunt infection. Determining the coagulase status of the isolate will allow differentiation between S. aureus and coagulase-negative staphylococci, likely S. epidermidis.

TREATMENT OF CEREBROSPINAL FLUID SHUNT INFECTIONS

CASE 65-4, QUESTION 2: Culture and sensitivity tests of T.A.'s ventricular fluid are positive for S. epidermidis. The isolate is resistant to nafcillin but sensitive to vancomycin, rifampin, and TMP-SMX. How should T.A.'s CSF shunt infection be treated?

For T.A.'s CSF shunt infection to be optimally treated, a combined medical and surgical approach is required. Studies have demonstrated poorer outcomes for systemic antibiotic therapy alone versus systemic antibiotic therapy plus shunt removal.[100] Because many patients cannot tolerate the complete removal of their shunt for long, externalization of the distal end of the shunt, or shunt removal and placement of an external drainage device, often is necessary during systemic antibiotic therapy. The presence of an externalized device permits sequential sampling of ventricular fluid and also provides a convenient way to administer antibiotic intraventricularly (see the following discussion entitled Intraventricular Dosing of Vancomycin).

Glycocalyx

Although S. epidermidis is not as virulent a pathogen as S. aureus, it is extremely difficult to eradicate this organism from prosthetic devices such as CSF shunts. This is because many strains of S. epidermidis produce a mucous film or slime layer known as glycocalyx, which allows the staphylococci to adhere tightly to the shunt material, protecting them against phagocytosis.[101] As expected, antibiotic failures are much more likely with slime-producing strains of S. epidermidis.

Vancomycin is the drug of choice for treatment of shunt infections caused by S. epidermidis and should be instituted immediately in T.A.[11],[102] This is because a high percentage (>60%) of coagulase-negative staphylococci are resistant to methicillin (e.g., methicillin-resistant S. epidermidis [MRSE]). T.A.'s isolate also is sensitive to

TMP-SMX, as is the case with many strains of MRSE (and also methicillin-resistant S. aureus [MRSA]), but it must be avoided because T.A. is allergic to this drug combination. Although not considered a first-line therapy, linezolid has been shown to be effective for VP shunt infections in small case series and may be considered in vancomycin-allergic patients.[103],[104] Additionally, many staphylococcal isolates (both S. epidermidis and S. aureus) are susceptible to rifampin, but monotherapy with this drug is not recommended because of rapid emergence of resistance. However, rifampin may be used in addition to an antistaphylococcal agent to enhance bactericidal activity, especially if the prosthesis is retained.[102]

Vancomycin Therapy

CASE 65-4, QUESTION 3: What would be an appropriate IV dosage for vancomycin in T.A.? What subjective or objective data should be monitored to evaluate the efficacy and toxicity of the treatment?

Vancomycin therapy for T.A.'s CSF shunt infection requires the use of doses similar to those used for bacterial meningitis. For adults such as T.A., vancomycin dosages of 30 to 45 mg/kg/day have been endorsed.[11] For children with meningitis or infected shunts, the recommended dosage of vancomycin is 40 to 60 mg/kg/day, given IV in two to four divided doses (Table 65-6).[105] Targeted serum trough concentrations of vancomycin should be between 15 and 20 mcg/mL.[11],[32]

T.A., who weighs 60 kg, should be started on a vancomycin regimen of 1 g IV every 8 to 12 hours because her renal function is normal. In either case, trough serum concentrations should be obtained at steady state to assess whether the initial dosing regimen is adequate. Another consideration for T.A. is the addition of rifampin to her vancomycin regimen. This is based on the excellent staphylococcal activity of rifampin, its moderate CSF penetration, and the potential for synergy between these two agents.[106] Whether rifampin plus vancomycin is superior to vancomycin alone has not been determined. For T.A., it is best to avoid rifampin because evidence supporting its efficacy is weak, and she currently is taking phenytoin and oral contraceptives. Rifampin is a potent inducer of hepatic microsomal enzymes, which can lower serum phenytoin concentrations (possibly resulting in seizure activity) and increase the possibility of an unplanned pregnancy (from reduced effectiveness of the birth control pill).

Intraventricular Dosing of Vancomycin

CASE 65-4, QUESTION 4: Should T.A. receive intraventricular vancomycin? If so, what would be an appropriate dosage?

T.A. should receive IV vancomycin. In addition, T.A. has a long history of hydrocephalus and will require placement of an external drainage device after removal of her VP shunt. The external drainage device allows for intraventricular administration of vancomycin, and such treatment should be instituted promptly. Although dosage recommendations vary from 5 to 20 mg/day, most use 20 mg/day and this dose should be used for T.A. Also, serial (daily) cultures of CSF are recommended to monitor her response to therapy. Therapy should be continued for at least 10 days after sterilization of her ventricular fluid is documented, at which time a new VP shunt can be placed.[11]

In contrast to T.A.'s situation, vancomycin therapy for patients with MRSA meningitis not associated with a CSF shunt or indwelling ventricular catheter is more problematic. The latest MRSA clinical practice guidelines from 2011 endorse a 2-week course of IV vancomycin 15 to 20 mg/kg/dose IV every 8 to 12 hours, with the potential addition of rifampin 600 mg daily, or 300 to 450 mg every 12 hours. Additionally, in seriously ill patients, including those with meningitis, a loading dose of 25 to 30 mg/kg of actual body weight may be considered. Trough concentrations between 15 and 20 mcg/mL are recommended.[32] In the setting of drug allergy, intolerance, or adverse events, alternatives include linezolid 600 mg PO or IV every 12 hours, or TMP-SMX 5 mg/kg/dose IV every 8 to 12 hours.[107]

BRAIN ABSCESS

Epidemiology

Although not nearly as common as meningitis, abscesses of the brain parenchyma (brain abscess) remain an important type of CNS infection. The reported incidence of brain abscess caused by any type of organism ranges from 0.4 to 0.9 cases per 100,000 population.[108],[109] On a busy neurosurgical service, 4 to 10 cases a year typically are seen.[110],[111] For reasons that are not entirely clear, men are more likely to develop abscesses within the brain than women.[109],[110] Brain abscess can occur at any age, but the mean age most recently reported is 34 years of age, with a minority of cases occurring in children.[112]

Despite advances in antimicrobial therapy over the past several decades, mortality rates from brain abscess have remained above 40% until recently. Developments in imaging techniques (e.g., CT and MRI scanning), which allow early recognition of abscesses and the ability to serially monitor the radiographic response to antimicrobial therapy, have had the most profound impact on reducing morbidity and mortality from brain abscess. A recent meta-analysis of 123 studies found case fatality rates declined from 40% to 10% over the decades from 1970 to 2013 whereas the rates of full recovery increased from 33% to 70%. With the combined medical and surgical approach currently recommended, mortality rates continue to average <10%.[112]

Predisposing Factors

Brain abscesses most commonly arise from a contiguous suppurative source of infection (e.g., sinusitis, otitis, mastoiditis, or dental infections).[112] The formation of a single abscess cavity usually is found when infection develops from a contiguous source. In addition, the abscess nearly always is formed in close proximity to the primary focus of infection (Table 65-9). For example, abscesses of sinusitic origin more commonly involve the frontal lobe, whereas otitic infections often lead to temporal lobe abscess formation.[113] Brain abscess also occurs as a consequence of hematogenous spread of organisms from a primary site of infection (e.g., lung abscess, endocarditis, osteomyelitis, pelvic, and intra-abdominal infections). Multiple abscesses suggest a metastatic source of infection. As with meningitis, brain abscess occurs as an infrequent complication of head trauma or neurosurgery.[112] No identifiable source (cryptogenic abscess) is detected in as many as 30% of cases.[113]

Staging

Once an intracranial focus of infection is established, the evolution of brain abscess involves two distinct stages: cerebritis and capsule formation. The cerebritis stage evolves gradually over the first 9 to 10 days of infection and is characterized by an area of marked inflammatory infiltrate that contains a necrotic center surrounded by an area of cerebral edema. Capsule formation occurs about 10 to 14 days after the initiation of infection, and once formed, the capsule continues to thicken over a period of weeks. The stage of abscess development has important implications for therapy. Although it is best to wait until the capsule is fully formed before attempting any type of surgical intervention, antimicrobial therapy alone may resolve the infection if discovered in the early cerebritis stage.[114]

Microbiology

The microbiology of brain abscess is distinctly different from that of meningitis. Streptococci are implicated in 50% to 70% of cases and include anaerobic as well as microaerophilic streptococci of the S. milleri group.[112] Other anaerobes, particularly Bacteroides species (including B. fragilis) and Prevotella species, are the second most common cause of brain abscess and are usually in mixed culture.[110],[112] These organisms are followed by staphylococci and gram-negative bacteria as other common pathogens.[112] Although somewhat imprecise, a reasonable correlation exists between the various predisposing conditions and the microbiologic etiology of brain abscess (Table 65-9).[113]

Table 65-9

Predisposing Conditions, Microbiology, and Recommended Therapy for Bacterial Brain Abscess

Predisposing Condition	Usual Location of Abscess	Most Likely Organisms	Recommended Therapy
Contiguous Site			
Otitis media	Temporal lobe or cerebellum	Streptococci (anaerobic and aerobic), Bacteroides fragilis, gram-negative bacilli	Ceftriaxone + metronidazole
Sinusitis	Frontal lobe	Streptococci (predominantly), Bacteroides species, gram-negative bacilli, Staphylococcus aureus, Haemophilus species	Vancomycin + ceftriaxone + metronidazole
Dental infection	Frontal lobe	Fusobacterium species, Bacteroides species, and streptococci	Ceftriaxone + metronidazole
Primary Infection			
Head trauma or neurosurgery	Related to site of wound	Gram-negative bacilli, staphylococci, streptococci, Clostridium	Vancomycin + cefepime + metronidazole

In the immunocompromised patient, a diverse group of microorganisms can induce abscesses within the brain. In patients with AIDS, Toxoplasma gondii is the most common infectious cause of focal brain lesions.[115] Transplant recipients and those receiving immunosuppressive therapy are susceptible to infection from Nocardia species and fungi (e.g., aspergillus or candida species).[116] In Mexico and other Central American countries, cysticercosis remains a common cause of intracerebral infection.[117]

Clinical and Radiologic Features

CASE 65-5

QUESTION 1: L.Y., a 40-year-old man, is brought to the ED by a friend. L.Y. complains of severe headache, fever, weakness in his left arm and leg, and increasing drowsiness. During the past week, L.Y. has suffered from headaches, which have gradually worsened in intensity, and from intermittent episodes of fever. Despite getting plenty of sleep, L.Y. has been feeling increasingly drowsy during the past several days. When he noticed weakness in his left arm and difficulty concentrating this morning, he called a friend and asked to be taken in for evaluation.

L.Y. has a history of chronic sinusitis that has been treated with a variety of oral antibiotics. His last episode of sinusitis, which occurred about 1 month ago, was treated with a 10-day course of cephalexin. He denies any nausea or vomiting and has not experienced any seizures in the recent past. L.Y. was tested for HIV 6 months ago, and the result of his antibody test was negative. He takes no current medications, denies smoking and use of recreational drugs, and drinks alcohol only on social occasions a few times a month. L.Y. has no known drug allergies.

Physical examination reveals L.Y. to be in mild distress, with a temperature of 38.2°C. He is slightly lethargic and is oriented to person and place but not time. The strength in L.Y.'s left arm is 3/5; the strength in his left leg is 4/5. The remainder of his neurologic examination is grossly normal. L.Y. described moderate pain on palpation of his frontal sinuses, and a purulent discharge is noted.

Laboratory evaluation shows the following:

WBC count, 8,000 cells/μL, with 70% PMN, 25% lymphocytes, and 5% monocytes
BUN, 16 mg/dL
SCr, 1.2 mg/dL
Erythrocyte sedimentation rate (ESR), 40 mm/hour
Hgb, Hct, platelets, and serum chemistries are within normal limits.

A CT scan with contrast dye reveals a right frontal ring-enhancing lesion with a small amount of surrounding cerebral edema. L.Y. is admitted to the neurosurgery unit for further evaluation and treatment. What clinical signs and symptoms does L.Y. display that are suggestive of bacterial brain abscess? How can brain abscess be diagnosed in L.Y.?

L.Y. has presented to the ED with many signs and symptoms suggestive of bacterial brain abscess. He is 40 years of age and a man, both of which place him in a group with the highest likelihood of having a brain abscess. In contrast to the diffuse nature of meningitis, brain abscess presents as a focal neurologic process. Notable in L.Y.'s presentation is left-sided (arm and leg) weakness. Symptoms of brain abscess range in severity from indolent to fulminant, and in most patients, the duration of symptoms at the time of presentation is ≤2 weeks.[113] Headache is the most common symptom of brain abscess, occurring in approximately 70% of cases. L.Y.'s clinical manifestations have become gradually worse over the past week, and his worsening headaches, increasing drowsiness, and difficulty in concentrating all are consistent with bacterial brain abscess.

L.Y. presents with the classic triad of fever, headache, and focal neurologic deficits. Although this triad should always be looked for, fewer than half of patients with confirmed bacterial brain abscess present in this manner.[112]

The absence of fever does not rule out infection because fever is found in <50% of patients.[110],[113] Focal neurologic deficits are present in approximately 50% of patients and vary in nature and severity in relation to the location and size of the abscess and surrounding cerebral edema. Although L.Y. does not have a history of seizure activity, approximately 25% of patients experience partial seizures that often become generalized. Papilledema and nuchal rigidity occur in ≤25% of cases and often are not useful in confirming the diagnosis. Symptoms associated with a contiguous focus of infection should always be sought, and in some situations, they may dominate the clinical picture.[112] L.Y. has a history of sinus infection, and the pain on palpation of his sinuses coupled with the purulent sinus drainage suggests active infection at this site.

As can be seen from L.Y.'s test results, laboratory evaluation usually is not very helpful when diagnosing brain abscess. L.Y. does not have a peripheral leukocytosis, but he does have an elevated ESR. A normal peripheral WBC count is not unusual in patients with intracranial suppuration. The ESR often is elevated in brain abscess, but this test is nonspecific and only indirectly supports the diagnosis.

L.Y. did not have a lumbar puncture because this procedure is contraindicated for diagnosing brain abscess. The diagnostic yield from CSF is low because chemistries (e.g., protein, glucose, WBC) usually are normal and culture of the CSF in patients with brain abscess is unlikely to yield the causative pathogen. More important, performing a lumbar puncture in patients with space-occupying lesions of the brain can produce cerebral herniation as a consequence of the shifting pressure gradient induced within the cranial vault after insertion of the lumbar puncture needle.[118]

Of paramount importance is the abnormality detected on the CT scan of L.Y.'s brain. When dye is injected before the CT scan, brain abscesses will appear to "ring enhance." Furthermore, cerebral edema can be identified as a variable hypodense region immediately surrounding the abscess cavity. As stated earlier, CT and MRI scanning techniques have revolutionized the diagnosis and treatment of brain abscess.[112],[119] In general, a good correlation exists between the clinical and radiologic response to therapy of bacterial brain abscess.

Treatment

CASE 65-5, QUESTION 2: How should L.Y.'s brain abscess be treated?

SURGICAL TECHNIQUES

A combined medical and surgical approach is the best form of therapy for L.Y.'s brain abscess. Response rates to antimicrobial therapy alone have been disappointing, and with a few exceptions, surgical intervention is necessary to ensure optimal results. Modern stereotactic neurosurgical techniques allow almost any brain abscess that is ≥1 cm in diameter to be drained via stereotactic aspiration, regardless of location. Primary medical therapy may be indicated if imaging does not show a central cavity in the abscess or if surgery is withheld for other reasons such as poor health status.[113]

The two types of surgical approaches for brain abscess are (a) stereotactic navigation with needle aspiration and (b) intraoperative ultrasonography through a burr hole or craniotomy for direct abscess drainage.[113] Stereotactic aspiration of abscess is highly effective and is associated with lower morbidity and mortality than craniotomy.[120] Modern medical advances leave total resection with a very limited role unless an abscess is superficial or when there is high suspicion of fungal or tuberculous infection.[113]

ANTIMICROBIAL PENETRATION INTO BRAIN ABSCESS

Antimicrobial therapy is an essential component of brain abscess therapy. Penetration of antibiotics into brain abscess fluid has not been studied as carefully as penetration into CSF, and as discussed earlier, the barrier involved is different (Fig. 65-1).[7] Penicillins and cephalosporins penetrate adequately into abscess fluid, but certain agents (e.g., penicillin G) may be susceptible to degradation by enzymes present within the abscess milieu.[110] Third-generation cephalosporins (e.g., cefotaxime, ceftriaxone) penetrate sufficiently into the abscess and thus are appropriate choices when gram-negative bacteria are present.[110],[121] Metronidazole achieves abscess fluid concentrations equal to or in excess of serum levels and is bactericidal against strict anaerobes. The unique mechanism of action of metronidazole makes it particularly useful in the necrotic core of the cavity, where the oxidation-reduction potential is low and bacteria replicate slowly or are dormant. For these reasons, metronidazole is the drug of choice for anaerobic gram-negative bacterial brain abscess.[110] Vancomycin and carbapenems also penetrate sufficiently into brain abscess fluid.[110],[122] Although specific abscess-penetration data are unavailable, successful treatment of cerebral nocardiosis with TMP-SMX and CNS toxoplasmosis with clindamycin suggests that these compounds also achieve adequate penetration into cerebral abscess cavities.[123],[124]

ANTIBIOTIC THERAPY

When antibiotic therapy should be instituted depends on the status of the patient and the stage of abscess development. For patients diagnosed during the cerebritis stage, before formation of a well-circumscribed capsule, surgery should be delayed and antimicrobial therapy begun in patients with significant symptoms.[110],[121] If capsule formation already has taken place and if the patient's clinical status allows, it is reasonable to delay initiation of antibiotics until after surgery if surgery is to be performed within hours to increase the microbiologic yield from tissue and fluid samples. If the disease is fulminant, antibiotics must be instituted promptly and surgical intervention performed as quickly as possible.[113]

L.Y.'s clinical presentation suggests an advanced brain abscess. The presence of ring enhancement on CT and the onset of symptoms over 2 weeks support this conclusion. Because he is not critically ill, antibiotic therapy may be delayed until surgery is performed. Specimens obtained from the surgical procedure should be sent for aerobic and anaerobic culture and an immediate Gram stain.

Initial antibiotic therapy for brain abscess needs to be sufficiently broad to cover the most likely pathogens (Table 65-9). When the implicated source is contiguous such as oral, otogenic, or sinus, metronidazole plus ceftriaxone (with the addition of vancomycin with a sinus source) is recommended.[110],[113] Metronidazole will provide coverage for strict anaerobes, including Bacteroides and Prevotella species. When the implicated source is head trauma with skull fracture or is associated with a neurosurgical procedure, empiric therapy should consist of vancomycin, metronidazole, and a third- or fourth-generation cephalosporin. For hematogenous sources, a third-generation cephalosporin, metronidazole, and vancomycin are recommended.[113] Vancomycin is added to cover staphylococcal infection.

For L.Y., therapy with ceftriaxone 2 grams IV Q 12 hours, vancomycin 1 gram IV Q 8 hours, and metronidazole 500 mg IV Q 8 hours should be started postoperatively (Table 65-6).

ADJUNCTIVE CORTICOSTEROID THERAPY

Adjunctive corticosteroid therapy for bacterial brain abscess is controversial. Steroids can interfere with antibiotic penetration into abscesses and obscure the interpretation of serial CT scans when assessing response to therapy. Therefore, steroids are indicated only if significant cerebral edema is present, particularly if it is accompanied by rapid neurologic deterioration.[110,121] L.Y. should not receive dexamethasone because his mental status is only mildly depressed and the cerebral edema seen on CT scan is not massive.

ADJUNCTIVE ANTICONVULSANT THERAPY

L.Y. has shown no sign of seizure activity thus far and, therefore, does not require anticonvulsant therapy. Anticonvulsants should be used in the acute setting when seizures are present, however.[110,121] Agents with activity against partial and complex partial seizures are preferred (e.g., phenytoin, carbamazepine, and potentially levetiracetam). The long-term use of anticonvulsants depends on whether seizure activity persists. Insufficient information exists regarding how long to continue anticonvulsants in such cases. Therefore, discontinuation of these agents must be individualized.

No formal guidelines are available regarding the optimal duration of therapy for bacterial brain abscess. Given the serious nature of the infection and the difficulty associated with antibiotic penetration, therapy with high-dose IV therapy should continue for at least 6 to 8 weeks.[110,113] The duration of therapy should be evaluated on a case-by-case basis. In an attempt to ensure complete eradication of infection, some experts recommend long-term (2–6 months) oral antibiotics after the IV course, provided agents with good oral absorption and activity against the offending pathogens are available.[110]

MONITORING THERAPY

CASE 65-5, QUESTION 3: How should L.Y. be monitored for therapeutic response and toxicity?

Although L.Y. is on antibiotic therapy, weekly or biweekly CT scans should be obtained to evaluate abscess resolution. His clinical response to therapy also should be assessed daily. If therapy is effective, L.Y.'s mental status should improve gradually (e.g., he will become more alert and oriented) over a period of several days. L.Y.'s headaches and hemiparesis (weakness in his arm and leg) also should resolve eventually. It may take a week or longer, however, to see a complete resolution of symptoms.[110] In general, radiologic improvement (i.e., reduction in abscess size) correlates reasonably well with clinical response, but not always. Persistent symptoms or failure to detect a reduction in abscess size on CT scan or the appearance of new abscesses may indicate improper antimicrobial therapy or the need for more surgery.[110,121] Repeated surgical intervention with appropriate reculturing may be required in some instances to optimize therapy.

Adverse effects associated with the penicillin G therapy that L.Y. is receiving are similar to those of other β-lactam antibiotics. Seizures are a potential complication when high doses of penicillin are used in the presence of a mass lesion in the brain.[125] L.Y. should be observed closely by those providing care and questioned regularly for any evidence of seizure activity. Metronidazole usually is well tolerated, but may also cause neurotoxicity, most commonly peripheral neuropathy. L.Y. should be assessed for the presence of numbness or tingling in his hands or feet. Seizures, although uncommon, occasionally occur with metronidazole. If L.Y. experiences peripheral neuropathy or seizures, a switch to meropenem would be appropriate. Other adverse effects associated with metronidazole include mild nausea, brownish discoloration of the urine, and the potential for a disulfiram-like reaction with concomitant ethanol ingestion.[126] L.Y. should be counseled regarding the possibility of gastric upset and discoloration of the urine, and he should be strongly cautioned to avoid alcoholic beverages while receiving metronidazole. Given his young age, the absence of significant underlying diseases, and the relative early detection of his brain abscess, there is every reason to expect a good response to his treatment and, eventually, a complete resolution of his abscess.

Endocarditis

Michelle L. Chan and Annie Wong-Beringer

CORE PRINCIPLES	CHAPTER CASES
1 Infective endocarditis (IE) is a microbial infection of the heart valves or other endocardial tissue, usually associated with an underlying cardiac defect. Disease incidence has remained stable over time accounting for 15,000 to 20,000 new cases per year. Streptococcus viridans, Staphylococcus aureus, and Enterococcus species are common causes of IE. Other rare pathogens affecting special populations include Staphylococcus epidermidis, Pseudomonas aeruginosa, and Candida species.	**Case 66-1 (Question 1), Case 66-2 (Question 1), Case 66-3 (Question 1), Case 66-4 (Question 1), Case 66-5 (Questions 1, 4, 6)**
2 Clinical presentation may be highly variable and characterized by nonspecific symptoms such as fever, weight loss, fatigue, night sweats, and arthralgias. Peripheral manifestations specific to IE include conjunctival petechiae, Janeway lesions, and splinter hemorrhages. Major embolic episodes and infarction involving other organs can develop in up to one-third of cases. Congestive heart failure (CHF) is the most common cause of death in IE, and the most common indication for surgery.	**Case 66-1 (Question 1), Case 66-2 (Question 2), Figures 66-1–66-3**
3 The American Heart Association (AHA) recommends use of the modified Duke criteria as the primary diagnostic schema to evaluate patients suspected of IE. The most important factor confirming IE is positive blood cultures. Transesophageal echocardiogram (TEE) is a valuable tool to strengthen diagnosis and identify patients at risk for complications and need for surgical interventions.	**Case 66-1 (Question 2), Tables 66-1, 66-2**
4 General treatment approach to organism eradication requires the administration of parenteral bactericidal antibiotics at high doses for a prolonged duration of 4 to 6 weeks. Combination therapy may be needed to achieve synergy for some pathogens. Selection of regimen should be based on organism sensitivity, tissue penetration, and host tolerance of the antibiotic agent(s). The AHA treatment guideline by organisms should be followed.	**Case 66-1 (Questions 3, 4), Case 66-2 (Question 3), Case 66-3 (Questions 2–4), Case 66-4 (Questions 1–5), Case 66-5 (Questions 2, 3, 5, 7), Tables 66-3–66-5**
5 Treatment of IE caused by methicillin-resistant Staphylococcus aureus (MRSA) and by enterococci presents significant challenges owing to emergence of resistance to standard therapy, vancomycin. Higher doses of vancomycin targeting a trough concentration of 15 to 20 mcg/mL are advocated for treatment of MRSA IE, but may be associated with increased incidence of nephrotoxicity. Alternative agents for treatment	**Case 66-3 (Questions 3, 4), Case 66-4 (Question 5)**

	of IE caused by vancomycin-resistant enterococci have limited clinical success or lack of clinical evidence.	
⑥	Fungal endocarditis is rare, but carries poor prognosis. It occurs primarily in intravenous (IV) drug users, patients with prosthetic heart valves or IV catheters, and those with a compromised immune system. Management generally requires early valve replacement and combination antifungal therapy.	**Case 66-5 (Questions 1–3)**
⑦	The AHA recommends the use of antibiotic prophylaxis in select patients with specific cardiac conditions associated with the highest risk of adverse outcomes from endocarditis, who are undergoing dental or respiratory procedures known to cause significant bacteremia. Antimicrobial prophylaxis should be directed against the viridans group of streptococci.	**Case 66-6 (Questions 1, 2), Tables 66-6 and 66-7**

INFECTIVE ENDOCARDITIS

IE is a microbial infection of the heart valves or other endocardial tissue, often associated with an underlying cardiac defect. IE is classified based on the causative organism to provide information on the probable cause and course of the disease (acute or subacute), the likelihood of underlying heart disease, and the appropriate antimicrobial regimens.[1]

Pathogenesis

The pathogenesis of endocarditis involves a complex series of events that ultimately result in the formation of an infected platelet-β-fibrin thrombus on the valve surface.[1],[2] This thrombus is called a vegetation.

The first step in the formation of the vegetation involves modification of the endocardial surface, which is normally nonthrombogenic.

Valvular insufficiency caused by aortic stenosis or ventricular septal defects can produce regurgitant blood flow, high-pressure gradients, or narrow orifices, resulting in turbulence and endocardial damage.[1],[2] In patients with rheumatic heart disease, endocardial injury (e.g., mitral valve stenosis) occurs as a result of immune complex deposition or hemodynamic disturbances.

Once the endocardial surface of the valve is traumatized, small, sterile thrombi consisting of platelets and fibrin are deposited, forming the lesion called nonbacterial thrombotic endocarditis (NBTE).[1],[2] NBTE occurs most commonly on the atrial surfaces of the mitral and tricuspid valves and on the ventricular surface of the aortic valve.

NBTE serves as a nidus for microbial colonization during periods of bacteremia (e.g., procedures involving perforation of the oral mucosa, respiratory tract, genitourinary tract, or infected skin). Organisms such as Streptococcus viridans group, Enterococcus species, Staphylococcus aureus, Staphylococcus epidermidis, Pseudomonas aeruginosa, and Candida albicans possess adherence factors that facilitate their pathogenicity. In particular, platelet aggregation has been shown to be an important virulence factor in experimental streptococcal endocarditis potentially leading to larger vegetations and multifocal embolic spread.[3] Once the NBTE lesion becomes colonized by microorganisms, the surface is rapidly covered with a sheath of fibrin and platelets. This avascular encasement provides an environment protected from host defenses and is conducive to further bacterial replication and vegetation growth.[2] The bacterial colony count can be as high as 10^4 to 10^5 bacteria per gram of valvular vegetation.

Endocarditis can result in life-threatening hemodynamic disturbances and embolic episodes affecting many organs. Without antimicrobial therapy and surgical intervention, IE is virtually 100% fatal. Because of bacterial proliferation to high densities in the fibrin mesh protected from normal host defenses, cure of infection requires prolonged therapy of 4 to 6 weeks with relapse not uncommon.

Epidemiology

In 2009, there were 38,976 hospital admissions of endocarditis with an hospital mortality rate of 14% to 20%.[4],[5] The overall incidence has been stable; however, health–care-associated IE has emerged as a result of increased use of invasive medical devices and procedures (e.g., IV catheters, total parenteral nutrition [TPN] IV lines, hemodialysis shunts or fistulas, intracardiac prosthesis, central venous pressure monitoring lines).[1] With the exception of IV drug users, the mean patient age has shifted from younger than 30 years in the 1920s to older than 55 years today.[4],[6] This increase in age is likely attributable to (a) a decline in the incidence of acute rheumatic fever and rheumatic heart disease counterbalanced by degenerative valvular disease in an increasing elderly population, (b) the increasing longevity of the general population, and (c) increased exposure to more intense and invasive medical procedures in both the overall and the aging populations. Men are infected more often than women (roughly 2:1), and the disease remains uncommon in children, primarily in association with underlying congenital cardiac defect and nosocomial catheter-related bacteremia.[1]

Predisposing Factors

In general, any structural cardiac defect that leads to the turbulence of blood flow predisposes to the development of IE. Rheumatic heart disease was at one time the most common underlying cardiac defect associated with endocarditis; however, the proportion of cases related to rheumatic heart disease have declined to 25% or less in developed countries while remaining the predominant defect in developing countries.[4],[5] Mitral valve prolapse with thickened leaflets and valvular redundancy is a recognized predisposing risk to IE, with a documented occurrence rate of 10%. Clinical presentation is often subtle with lower associated mortality in these individuals compared with left-sided IE of other types. In the absence of underlying valvular defects, degenerative cardiac lesions, such as calcified mitral annulus secondary to atherosclerotic cardiovascular disease and postmyocardial infarction thrombus, may be a significant risk factor for the elderly. IV drug users constitute a unique population at greatest risk for recurrent and polymicrobial IE.[4]

Hemodialysis dependency (8%), diabetes mellitus (16%), and congenital heart disease (12%) are the most common demographic characteristics associated with IE.[7] Up to 25% of all cases are acquired in health-care-related settings. Notably, in the United States, health-care-associated IE is more likely compared with community acquisition.

Bacteriology

Streptococci and staphylococci are the cause of 80% to 90% of cases of IE. When comparing epidemiologic studies in the aggregate during the past decades, staphylococci are increasingly prevalent as a cause of IE. Viridans streptococci remain the predominant cause of IE in children and in young women with isolated mitral valve involvement.[1]

Staphylococcus aureus is the leading cause of IE.[7],[8] Acquisition of IE in nearly half of these cases was likely health-care-related, supporting a low threshold to evaluate underlying IE in the setting of health-care-related S. aureus bacteremia. More importantly, methicillin-resistant strains account for up to 40% of IE cases involving S. aureus.[4],[6]

Endocarditis in IV drug users often is caused by S. aureus, whereas prosthetic valve endocarditis (PVE) is more commonly caused by coagulase-negative staphylococci, such as S. epidermidis. Gram-negative bacilli and fungi together account for less than 10% of all endocarditis cases, which usually are associated with IV drug use, valvular prostheses, and hospital IV access procedures. Endocarditis caused by anaerobes and other organisms is rare. Polymicrobial IE (caused by at least two organisms), although uncommon in the typical patient, is being recognized more frequently in IV drug users and certain postoperative patients. Candida species, S. aureus, P. aeruginosa, Serratia marcescens, and non-β hemolytic group D streptococci are the organisms involved most frequently in these populations.

Site of Involvement

The site of heart valve involvement is determined by the underlying cardiac defect and the infecting organism.[2,4,6,7] The mitral valve is affected in more than 85% of cases caused by viridans streptococci with underlying rheumatic heart disease. The tricuspid valve is the common site of involvement in staphylococcal endocarditis associated with IV drug use. Overall, the distribution ranges from 28% to 45% for mitral valve, 5% to 36% for aortic valves, and 0% to 6% for tricuspid valves, and the pulmonary valve is rarely affected.[9] Multiple heart valves may be affected simultaneously. Some studies have shown that aortic valve involvement is increasing in frequency and is associated with higher morbidity and mortality.

STREPTOCOCCUS VIRIDANS GROUP ENDOCARDITIS

Clinical Presentation

CASE 66-1

QUESTION 1: A.G., a 57-year-old, 60-kg man with chief complaints of fatigue, a persistent low-grade fever, night sweats, arthralgias, and a 7-kg unintentional weight loss, is admitted to the hospital for evaluation. Visual inspection reveals a cachectic, ill-appearing man in no acute distress. Physical examination is significant for a grade III/IV diastolic murmur with mitral regurgitation (insufficiency) increased from preexisting murmur, a temperature of 100.5°F, petechial skin lesions, subungual splinter hemorrhages, and Janeway lesions on the soles of both feet (Figs. 66-1, 66-2, and 66-3). Nail clubbing, Roth spots, or Osler nodes are not evident. The remainder of his physical examination is unremarkable. A.G.'s medical history is significant for mitral valve prolapse and, more recently, a dental procedure involving the extraction of four wisdom teeth. The history of his present illness is noteworthy for the development of symptoms 2 weeks after the dental procedure (about 2 months before admission). His only current medication is ibuprofen 600 mg orally 4 times a day (QID).

Relevant laboratory results include the following:

Hemoglobin (Hgb), 11.4 g/dL (SI units, 114 g/L [normal, 140–180])
Hematocrit (Hct), 34% (SI units, 0.34 [normal, 0.39–0.49])
Reticulocyte count, 0.5% (SI units, 0.005 [normal, 0.001–0.024])
White blood cell (WBC) count, 35,000/μL with 65% polys and 1% bands (SI units, 35 × 10/L with 0.65 polys and 0.01 bands [normal, 3.2–9.8 with 0.54–0.62 polys and 0.03–0.05 bands])
Blood urea nitrogen (BUN), 21 mg/dL (SI units, 7.5 mmol/L of urea [normal, 2.9–8.9])
Serum creatinine (SCr), 1.2 mg/dL (SI units, 159 mmol/L [normal, 53–133])

A urinalysis (UA) reveals 2+ proteinuria and 10 to 20 red blood cells (RBCs) per high-power field (HPF). The erythrocyte sedimentation rate (ESR) is elevated at 66 mm/hour (normal, ≤30 mm/minute), and the rheumatoid factor (RF) is positive. Results from a transthoracic echocardiogram (TTE) were unrevealing.

Three blood cultures were obtained during 24 hours, and all cultures obtained on day 1 are growing gram-positive cocci in pairs and chains, presumed α-hemolytic streptococci. Although confirmation and speciation of the organism is being performed, A.G. is started on penicillin G, 2 million units IV every 4 hours (12 million units/day), and IV gentamicin, 120 mg (loading dose) followed by 60 mg every 12 hours. Antimicrobial susceptibility results are pending. What clinical manifestations and laboratory abnormalities in A.G. are consistent with IE?

The clinical presentation of IE is highly variable and can involve almost any organ system.[1] A.G. appears pale and chronically ill, and represents the typical patient with subacute disease (e.g., that caused by viridans streptococci). Nonspecific complaints consistent with endocarditis in A.G. include fatigue, weight loss, fever, night sweats, and arthralgias. Fever alone is present in most (90%) patients with endocarditis. The fever is characteristically low grade and remittent, with peaks in the afternoon and evening. Fever may be absent or minimal in patients with CHF, chronic renal and liver failure, prior use of antimicrobial agents, or IE caused by less virulent organisms.[1] Musculoskeletal complaints (e.g., arthralgias, myalgias, and back pain) are common and may mimic rheumatic disease. Other symptoms can include lethargy, anorexia, malaise, nausea, and vomiting.[1] Because signs and symptoms are nonspecific and subtle, diagnosis is often difficult to make. In addition, the time from bacteremia to diagnosis is often prolonged because of the insidious progression of symptoms.[1] Delayed diagnosis occurs more commonly in the elderly. Fever may be absent in 30% to 40% of patients older than 60 years of age, whereas it can be present in more than 90% of patients younger than 40 years of age. Elderly patients are less likely to have new or changed heart murmurs. The most common presenting complaints in the elderly with endocarditis are confusion, anorexia, fatigue, and weakness, which may be readily attributable to stroke, heart failure, or syncope.

The temporal relationship between A.G.'s dental procedure and the onset of symptoms suggests it was the etiology of bacteremia and subsequent endocarditis. Although it is assumed that prophylactic antibiotics were administered before the procedure, endocarditis can develop despite receipt of adequate chemoprophylaxis.[1,7,9]

A.G. has an increase in his preexisting diastolic murmur with mitral insufficiency, a finding consistent with endocarditis. Cardiac murmurs are present in more than 85% of patients with endocarditis. Murmurs frequently are absent in patients with acute disease (e.g., staphylococcal endocarditis), right-sided disease (e.g., endocarditis in IV drug users), or mural infection.[1]

A.G. exhibits several peripheral manifestations of IE, including conjunctival petechiae, Janeway lesions, and splinter hemorrhages. Overall, peripheral manifestations are observed in 10% to 50% of cases, but none of these is pathognomonic for IE.[1] These manifestations are usually a result of septic embolization of vegetations to distal sites, or immune complex deposition. Mucocutaneous petechial lesions of the conjunctiva, mouth, or pharynx are present in 20% to 40% of patients, especially those with long-standing disease.[1] These lesions generally are small, nontender, and hemorrhagic in appearance, and occur as a result of vasculitis or peripheral embolization. Janeway lesions are painless, hemorrhagic, macular plaques most commonly found on the palms and soles (Fig. 66-1). Splinter hemorrhages are nonspecific findings that appear as red to brown linear streaks in the proximal portion of the fingers or toenails (Fig. 66-2). Other findings can include Roth spots (small, flame-shaped retinal hemorrhages with pale white centers found near the optic nerve) and Osler nodes (purplish, nonhemorrhagic, painful nodules that develop on the subcutaneous pads of the fingers and toes or on palms and soles) Clubbing (broadening and thickening) of the nails also may be observed in patients with prolonged disease. Petechial skin lesions also are seen (Fig. 66-3).

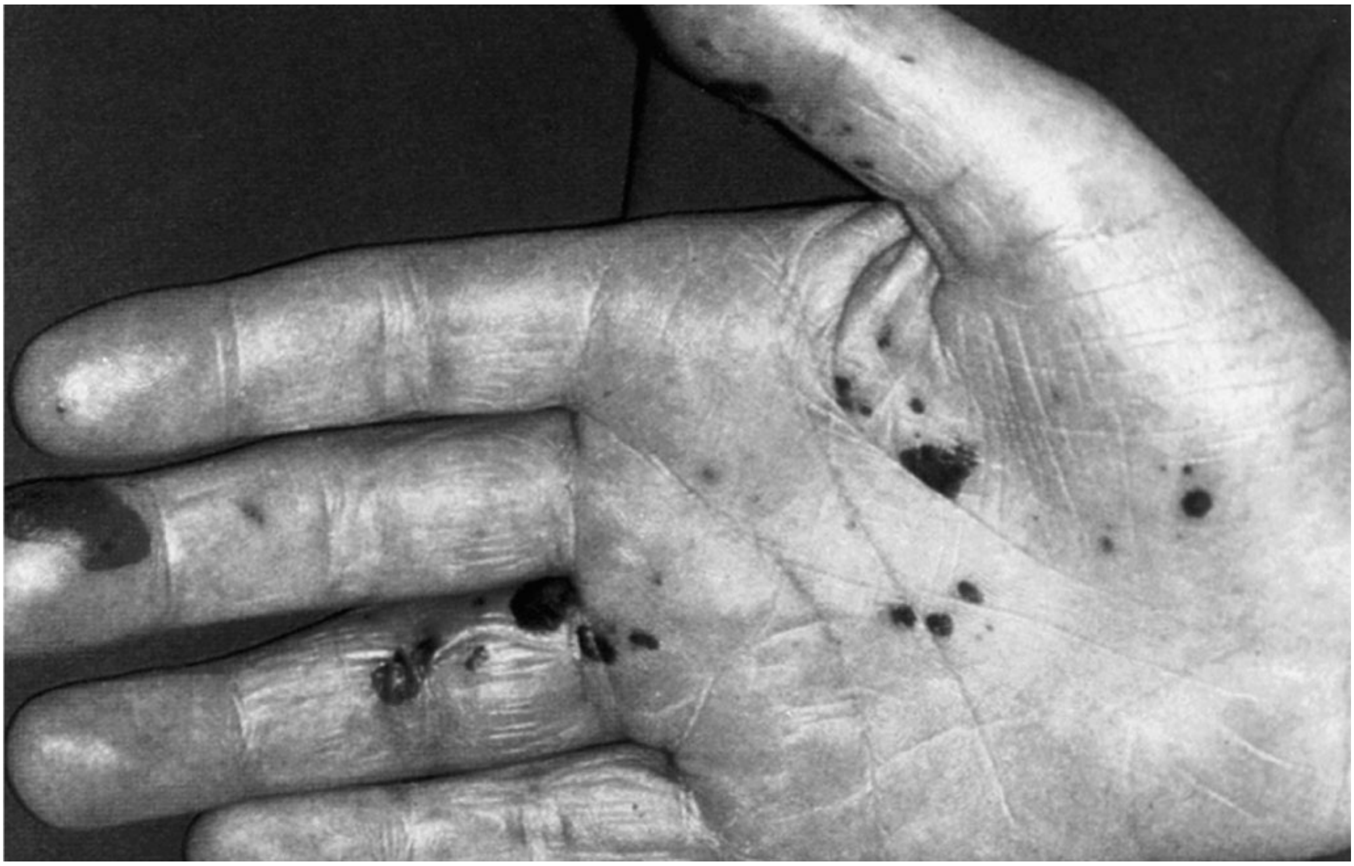

Figure 66-1 Janeway lesions. Extensive ecchymotic embolic lesions in a case of acute bacterial endocarditis.

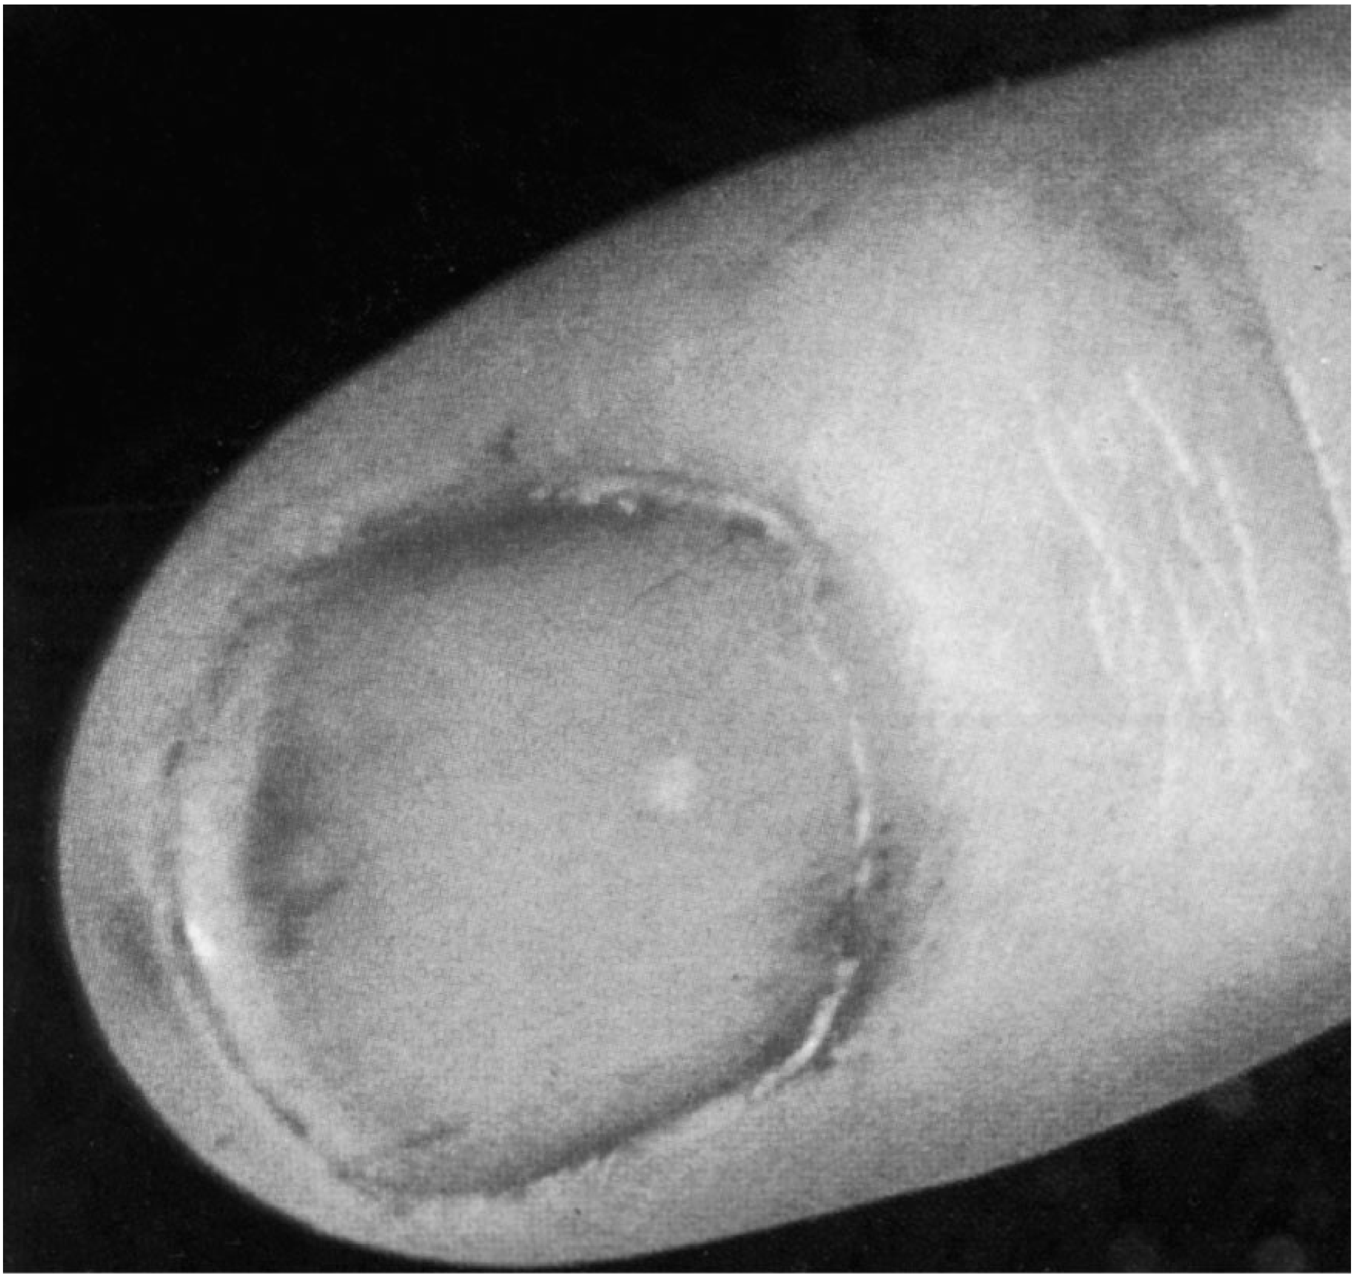

Figure 66-2 Splinter hemorrhages in the nail bed.

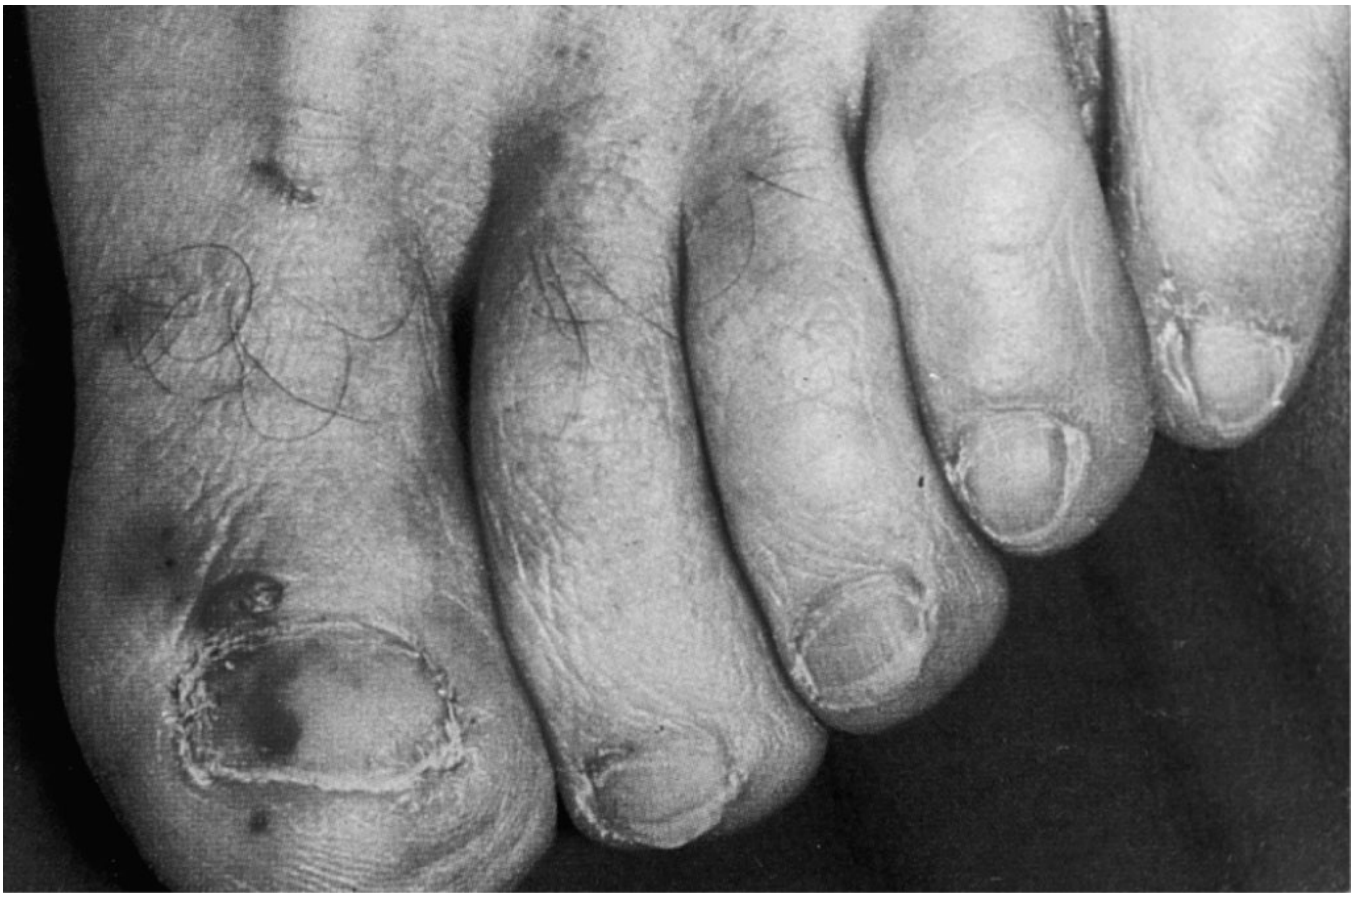

Figure 66-3 Petechial skin lesions in a case of acute staphylococcal endocarditis.

Several laboratory findings are consistent with IE in A.G. A low Hgb and Hct with normal red cell indices suggest anemia of chronic disease. Of patients with subacute disease, 70% to 90% will have a normochromic, normocytic anemia. Leukocytosis with a left shift, although not evident in A.G., commonly is seen in those with acute, fulminant disease such as staphylococcal endocarditis. The ESR nearly always is elevated in IE, but this finding is nonspecific and can be associated with several other disease entities. RF (an immunoglobulin M antiglobulin) and circulating immune complexes can be detected in most patients with long-standing disease, but both are nonspecific findings.[1]

Major embolic episodes and infarction involving the kidney, spleen, lung, and brain may develop as secondary complications in up to one-third of cases.[1] A.G. exhibits some degree of renal damage, as evidenced by moderate hematuria and proteinuria. Alterations in A.G.'s renal function (increased BUN and creatinine) probably are a result of immune complex deposition (diffuse glomerulonephritis) or secondary to renal embolization (focal glomerulonephritis). Erythrocyte and leukocyte cast formation also may be present. Renal impairment usually is reversible with the institution of effective antimicrobial therapy.[1],[10]

Cardiac complications occur most frequently. CHF from infection-induced valvular damage is the most common cause of death in IE and is the most common indication for surgery.[1],[10] As many as two-thirds of patients with endocarditis develop CHF. Aortic valve infection is more frequently associated with CHF than mitral valve infection. Other manifestations include paravalvular abscesses, pulmonary edema, and pericarditis.[10] Mitral valve injury caused by viridans streptococci generally is better tolerated hemodynamically than aortic valve injury caused by staphylococci. Although A.G. has no apparent signs of overt heart failure, he should be monitored closely for the development of hemodynamic instability.

Neurologic complications, most commonly stroke, rank second to cardiac complications in frequency, but they may be the leading cause of death in patients with endocarditis.[10] A stroke syndrome in a patient with underlying valvular abnormalities should prompt the clinician to rule out IE. Other clinical manifestations include headache, mental status change, transient ischemic attack, seizures, brain abscess, or intracranial mycotic aneurysms.[1,10] Neurologic symptoms associated with high mortality can be observed in up to 35% of S. aureus endocarditis patients who are not drug addicts.[11]

Metastatic abscesses can develop in virtually any organ secondary to systemic septic embolization. The most commonly involved metastatic foci are the spleen, kidney, liver, and iliac and mesenteric arteries.[10] Splenomegaly, although not part of A.G.'s findings, occurs in 20% to 60% of all cases and is more common in subacute disease.

Diagnosis

CASE 66-1, QUESTION 2: How was the diagnosis of IE established in A.G.?

BLOOD CULTURES

Although A.G.'s medical history (mitral valve prolapse, recent dental procedure) and clinical presentation are highly suggestive of IE, blood culture is the single most important diagnostic workup for IE.[1] Bacteremia (when present) secondary to endocarditis is continuous and low grade; more than 50% of the cultures show only 1 to 30 bacteria/mL. Despite the low concentration of organisms, at least one of the first two blood cultures is positive in 95% of cases.[1] In order to achieve a high yield, at least three sets of blood cultures collected by separate venipunctures should be obtained during the first 24 hours of presentation.[1] Administration of antibiotics within the previous 2 weeks may significantly decrease this yield.[12]

It is also important to establish the exact microbiologic cause before initiating antimicrobial therapy. In patients who are acutely ill, empiric therapy should start as soon as the appropriate cultures are obtained to avoid further valvular damage or other complications.[1]

ECHOCARDIOGRAPHY

Echocardiography is a valuable tool in establishing early diagnosis (e.g., the presence and size of vegetations), identifying patients at high risk for complications, and optimizing the timing and mode of surgical intervention by detecting and monitoring associated pathologic changes such as valvular abscess.[1],[13],[14] The transducer may be placed on the chest (transthoracic echocardiogram [TTE]) or in the esophagus (transesophageal echocardiogram [TEE]).[14] TTE is a rapid and noninvasive procedure with 98% specificity for vegetations. Sensitivity for vegetations may be less than 60% to 70%, however, for adult patients with obesity, hyperinflated lungs caused by emphysema, or a prosthetic valve. TEE is more costly and invasive, but is significantly more sensitive in detecting vegetations while maintaining high specificity. All patients with suspected IE should have echocardiography on admission and repeated during their course, to help guide future medical management and timing of intervention.[14] In particular, compared with TTE, TEE is superior in the diagnosis of pacemaker IE and IE in the elderly. A.G. has a negative TTE result on admission. Given the high clinical suspicion for IE in A.G., a follow-up TEE is recommended to rule out a false-negative TTE result.

In summary, IE should be suspected in any patient who has a documented fever and heart murmur and a preceding risk of bacteremia. Prior cardiac disease, peripheral manifestations, splenomegaly, various laboratory abnormalities, and a positive echocardiogram strengthen the diagnosis, but microbiologic documentation is the most important factor in confirming IE. Disease entities with overlapping clinical presentation and laboratory abnormalities should be excluded using the appropriate tests.[1]

Diagnostic criteria for IE which integrate clinical, laboratory, microbiologic, and echocardiographic data are listed in Tables 66-1 and 66-2.[7],[15] Based on published evidence involving nearly 2,000 patients, the 2015 AHA guidelines suggest that the modified Duke criteria be used as the primary diagnostic schema to evaluate patients suspected of IE.[7]

Table 66-1

Definition of Infective Endocarditis (IE) According to the Modified Duke Criteria

Definite IE[a]
PATHOLOGIC CRITERIA
Microorganisms: demonstrated by culture or histology examination of a vegetation, a vegetation that has embolized, or an intracardiac abscess specimen; or
Pathologic lesions: vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis
CLINICAL CRITERIA
Using specific definitions listed in Table 66-2; two major criteria or one major and three minor criteria or five

minor criteria
Possible IE
One major criterion and one minor criterion; or three minor criteria
Rejected
Firm alternative diagnosis explaining evidence of IE; or
Resolution of IE syndrome with antibiotic therapy for <4 days; or
No pathologic evidence of IE at surgery or autopsy, with antibiotic therapy for <4 days; or not meet criteria for possible IE as above

[a] Modifications shown in bold.

Table 66-2

Definitions of Terminology Used in the Modified Duke Criteria for the Diagnosis of Infective Endocarditis (IE)

Major Criteria[a]
BLOOD CULTURE POSITIVE FOR IE ■ Typical microorganisms consistent with IE from two separate blood cultures: 1. Viridans streptococci, Streptococcus bovis, HACEK group; or 2. Staphylococcus aureus or community-acquired enterococci in the absence of a primary focus; or ■ Microorganisms consistent with IE from persistently positive blood cultures defined as follows: 1. At least two positive blood cultures drawn >12 hours apart; or 2. All of three or a majority of four separate cultures of blood (with first and last sample drawn at least 1 hour apart) ■ **Single positive blood culture for Coxiella burnetii or antiphase 1 IgG antibody titer >1:800**
EVIDENCE OF ENDOCARDIAL INVOLVEMENT ■ Echocardiogram positive for IE **(TEE recommended for patients with prosthetic valves, rated at least “possible IE” by clinical criteria or complicated IE [paravalvular abscess]; TEE as first test in other patients)** defined as follows: 1. Oscillating intracardiac Masson valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation; or 2. Abscess; or 3. New partial dehiscence of prosthetic valve ■ New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)
Minor Criteria
■ Predisposition: Predisposing heart condition or IV drug use ■ Fever >38°C (100.4°F) ■ Vascular Phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions ■ Immunologic Phenomena: glomerulonephritis, Osler nodes, Roth spots, RF ■ Microbiologic Evidence: positive blood culture but not meeting major criterion as noted above[b] or serologic evidence of active infection with organism consistent with IE ■ **Echocardiographic minor criteria eliminated**

[a] Modifications shown in bold.

[b] Excludes single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis.

HACEK, Haemophilus species, Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella species, and Kingella kingae; TEE, transesophageal echocardiography.

Reprinted with permission from Li JS et al. Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. Clin Infect Dis. 2000;30:633.

A.G. possesses one major criterion (positive blood cultures) and three minor criteria (fever, predisposing heart condition, vascular and immunologic phenomena); therefore, he meets the diagnostic criteria for definite IE.[15]

Antimicrobial Therapy

GENERAL PRINCIPLES

CASE 66-1, QUESTION 3: What would be a reasonable duration of antibiotic therapy for A.G.? When is determination of minimum bactericidal concentration (MBC) useful in treating bacterial endocarditis?

The avascular nature of the vegetation results in an environment that is devoid of normal host defenses (e.g., phagocytic cells and complement); this permits uninhibited growth of bacteria.[2] Therefore, to eradicate the causative organism, high doses of an IV bactericidal antibiotic generally are administered for 4 to 6 weeks.[1],[7] For some infections, it may be necessary to use two antibiotics to achieve synergistic activity against the organism. Once an organism has been identified, its in vitro susceptibility pattern is determined by the minimum inhibitory concentration (MIC) for various antibiotics. Standard Kirby-Bauer disk diffusion testing is inadequate in the setting of IE to aid in selection of antibiotics without the quantitative information provided by the MIC.[1] In addition, the MBC may be useful in detecting tolerant strains, particularly in the setting of unexplained slow response or treatment failure. Routine MBC determination is not recommended, however.[1] Treatment of endocarditis requires antibiotics with bactericidal activity; therefore, the serum concentration of the antibiotic must greatly exceed the MBC for the particular organism. For endocarditis caused by viridans streptococci acquired from the community, this usually is achieved without much difficulty because most isolates are sensitive to penicillin at an MIC of less than 0.12 mcg/mL[7]; corresponding MBCs are, at most, one or two tube dilutions higher.[9] The emergence of strains demonstrating resistance to penicillin and related β-lactams, such as ceftriaxone, is a significant problem, particularly among bloodstream isolates obtained from the nosocomial setting and neutropenic cancer patients.[9],[16],[17] The increasing prevalence of β-lactam-resistant clinical isolates highlights the importance of determining the MIC and continued close monitoring of the antibiotic susceptibility of viridans streptococci. An increasing number of reports have described suboptimal response to vancomycin therapy for the treatment of invasive infection caused by methicillin-resistant S. aureus (MRSA) strains showing borderline susceptibility (MIC 2 mcg/mL).[18],[19] Many such strains demonstrated tolerance to vancomycin as defined by a high MBC-to-MIC ratio (≥32).[20] Thus, these data support the need to determine MBC, especially in the setting in which the treatment option for IE caused by S. aureus is limited to vancomycin and suboptimal response is observed.[20]

REGIMEN SELECTION

CASE 66-1, QUESTION 4: What factors must be considered in selecting a regimen for A.G.? Which regimen should be used for A.G.?

Patients with endocarditis caused by penicillin-sensitive strains of viridans streptococci and nonenterococcal group D streptococci (e.g., Streptococcus gallolyticus; MIC <0.1 mcg/mL) can be treated with any one of three regimens as outlined in the 2015 AHA treatment guidelines.[7] The suggested regimens (Table 66-3) are associated with cure rates of up to 98% and include (a) high-dose parenteral penicillin for 4 weeks, (b) high-dose parenteral ceftriaxone for 4 weeks, and (c) 2 weeks of combined therapy with high-dose parenteral penicillin and an aminoglycoside.[7],[21–27] Ceftriaxone with an aminoglycoside for 2 weeks appears to be equally effective.[28],[29]

Table 66-3

Suggested Regimens for Therapy of Native Valve Endocarditis Caused by Streptococcus viridans group and Streptococcus gallolyticus

Antibiotic	Dose[a],[b] and Route	Duration
Penicillin-Susceptible [minimum inhibitory concentration (MIC) ≤0.12 mcg/mL]		
Aqueous crystalline penicillin G[c]	Adult: 12–18 million units/24 hour IV either continuously or in four to six equally divided doses	4 weeks
	Pediatric: 200,000 units/kg/24 hour IV (max: 20 million units/24 hour) either continuously or in four to six equally divided doses	
Ceftriaxone sodium[c]	Adult: 2 g once daily IV or IM	4 weeks
	Pediatric: 100 mg/kg once daily IV or IM	
Aqueous crystalline penicillin G	See penicillin-susceptible dosing for penicillin above	2 weeks

Ceftriaxone sodium	See penicillin-susceptible dosing for ceftriaxone above	2 weeks
With gentamicin sulfate[d]	Adult: 3 mg/kg once daily IV or IM	2 weeks
	Pediatric: 3 mg/kg once daily IV or IM or in three equally divided doses	
Relatively Penicillin G Resistant (MIC >0.12 mcg/mL and <0.5 mcg/mL)		
Aqueous crystalline penicillin G	Adult: 24 million units/24 hour IV either continuously or in four to six equally divided doses	4 weeks
	Pediatric: 200,000–300,000 units/kg/24 hour IV (max: 20 million units/24 hour) either continuously or in four to six equally divided doses	
With gentamicin sulfate[d]	Adult: 3 mg/kg once daily IV or IM Pediatric: 3 mg/kg once daily IV or IM or in three equally divided doses	2 weeks
Ceftriaxone sodium	Adult: 2 g once daily IV or IM Pediatric: 100 mg/kg once daily IV or IM	4 weeks
β-Lactam Allergic Patients		
Vancomycin hydrochloride[e]	Adult: 30 mg/kg/24 hour IV in two equally divided doses (max: 2 g/24 hour unless serum concentrations are monitored)	4 weeks
	Pediatric: 40 mg/kg/24 hour IV in two or three equally divided doses (max: 2 g/24 hour unless serum concentrations are monitored)	

[a] Pediatric doses should not exceed that of a normal adult.

[b] Antibiotic doses for patients with impaired renal function should be modified appropriately.

[c] Preferred in most patients >65 years of age and in those with impairment of the eighth nerve or renal function.

[d] Two-week regimen not intended for patients with known cardiac or extracardiac abscess or for those with creatinine clearance of <20 mL/minute, impaired eighth cranial nerve function or Abiotrophia, Granulicatella, or Gemella infection. Gentamicin nomogram should be used for preferred single daily dosing; when three divided doses are used, dosage should be adjusted to achieve peak serum concentrations of 3–4 mcg/mL and trough serum concentrations of <1 mcg/mL. Other potential nephrotoxic drugs should be used with caution in patients receiving gentamicin therapy.

[e] Vancomycin dosage should be reduced in patients with impaired renal function. Vancomycin given on a milligram per kilogram basis produces higher serum concentrations in obese patients than in lean patients. Therefore, in obese patients, dosing should be based on adjusted body weight. Each dose of vancomycin should be infused for at least 1 hour to reduce the risk of the histamine-release red man syndrome. Trough concentrations should be obtained within half an hour of the next dose and be in the range of 10–15 mcg/mL.

IM, intramuscular; IV, intravenous.

Circulation. 2015;132:1435–1486.

HIGH-DOSE PENICILLIN FOR 4 WEEKS

Ten to 20 million units/day of IV penicillin G for 4 weeks resulted in a cure rate of 100% for 66 patients with nonenterococcal streptococcal endocarditis.[23] Another study using penicillin monotherapy reported relapse in only 2 of 49 patients; however, both of these patients received less than 4 weeks of therapy.[24] The large range of 12 to 18 million units/day of penicillin is recommended to allow flexibility in dosing based on the patient's renal function and disease severity. Ampicillin 2 g every four hours is a reasonable alternative.

SINGLE DAILY CEFTRIAXONE FOR 4 WEEKS

Ceftriaxone is active against viridans streptococcal strains isolated from patients with endocarditis. In one study, all 49 strains of viridans streptococci and 11 strains of S. bovis were inhibited at <0.125 mcg/mL of ceftriaxone; one strain of Streptococcus sanguinis was inhibited at an MIC of 0.25 mcg/mL.[30] Although no direct comparative trials have been performed evaluating ceftriaxone against high-dose penicillin for the treatment of streptococcal endocarditis, it appears to be comparable to high-dose penicillin when treatment is given for 4 weeks.[31],[32] Of the 70 assessable patients who received ceftriaxone 2 g as a single daily dose for 4 weeks, all were cured, except for one patient who had a probable relapse 3 months after completion of therapy. All strains of viridans streptococci were inhibited by ceftriaxone at an MIC of 0.25 mcg/mL in both studies. Although the simplicity of single daily treatment with ceftriaxone is attractive for outpatient use, careful patient selection based on microbiologic, clinical, and host factors is critical to the success of treatment and the proper and timely management of potential complications. (See Case 66-6, Question 1, for a detailed discussion of outpatient therapy.)

HIGH-DOSE PENICILLIN OR CEFTRIAXONE PLUS AN AMINOGLYCOSIDE FOR 2 WEEKS

The combination of 2 weeks of streptomycin (or gentamicin) with 4 weeks of penicillin is synergistically bactericidal for most streptococci, including enterococci (see Case 66-4, Question 4).[27],[33] This in vitro synergy also has been correlated with a more rapid rate of eradication of viridans streptococci from cardiac vegetations in the rabbit model.[25] A shortened combination regimen consisting of high-dose penicillin G and streptomycin for 2 weeks is an effective alternative to the previously described regimens. The reported cure rate in 104 patients treated at the Mayo Clinic with this regimen was 99%.[26],[27]

Although clinical experience with combination therapy has been primarily with penicillin and streptomycin, in vitro and animal data support that streptomycin and gentamicin are reasonably interchangeable. Administration of gentamicin once daily versus thrice daily when added to penicillin appears equally effective in the treatment of viridans streptococcal endocarditis.[21]

Combination therapy with ceftriaxone and aminoglycoside for 2 weeks has also been evaluated.[24],[28] Clinical cure rates of 87% to 96% were observed in patients infected with penicillin-susceptible streptococci when given once daily ceftriaxone 2 g plus netilmicin or gentamicin at 3 mg/kg. This study excluded patients with suspected or documented cardiac or extracardiac abscesses and those with PVE. Although the aminoglycoside agent (netilmicin or gentamicin) was administered as a single daily dose in both studies, all of the patients had measurable serum trough levels. Therefore, the efficacy of “extended-interval dosing” of aminoglycoside (whereby trough levels are not detectable, allowing a drug-free interval) in short-course combination therapy remains uncertain.

Based on available data, the 2-week regimen of penicillin or ceftriaxone plus an aminoglycoside appears to be efficacious for uncomplicated cases of penicillin-susceptible viridans streptococci endocarditis. It is not currently recommended for patients with extracardiac complications or intracardiac abscesses. Patients infected with Abiotrophia species (formerly known as nutritionally variant viridans streptococci) or viridans streptococci with a penicillin MIC greater than 0.1 mcg/mL or patients who have prosthetic valve infections should not receive short-course therapy.[7]

SPECIAL CONSIDERATIONS

The risk of relapse may be higher in patients who have had symptoms for more than 3 months before the initiation of treatment.[1,7,31] These patients should be treated with 4 to 6 weeks of penicillin combined with an aminoglycoside for the first 2 weeks.[1,7,31]

Nutritionally deficient or variant streptococci (NVS) have been reclassified into a new genus, Abiotrophia, which includes Abiotrophia defectiva, Abiotrophia adiacens (renamed again as Granulicatella adiacens), and Abiotrophia elegans. Abiotrophia species are slow-growing, fastidious organisms that are responsible for approximately 5% of IE cases.[34] Previously, NVS were the cause of most of the cases of endocarditis diagnosed as “culture-negative,” initially owing to its requirement for the addition of vitamin B_6 (pyridoxal HCl) to the culture media for laboratory growth. Laboratory identification is no longer a significant problem, however, because of current culture media and laboratory techniques.[9]

NVS are less susceptible to penicillin when compared with other streptococci. Many NVS have a relatively high MIC to penicillin (0.2–2.0 mcg/mL), and some show high-level resistance to penicillin (MIC >4 mcg/mL).[9] In addition, tolerance to penicillin has been described in many strains.[9] An animal model of endocarditis indicates that a penicillin–aminoglycoside (streptomycin or gentamicin) combination is significantly better than penicillin alone in reducing bacterial counts.[35] High rates of bacteriologic failure and relapse may be expected in patients despite completion of the treatment course for strains highly susceptible to penicillin.[9] All patients infected with NVS or Abiotrophia should receive 4 to 6 weeks of high-dose penicillin (or ampicillin) in combination with gentamicin.[7] A 6-week course of combination therapy with penicillin and gentamicin is recommended for patients with symptoms longer than 3 months in duration and those with PVE caused by these strains.[7,9] Patients with endocarditis caused by relatively resistant viridans streptococci with penicillin MIC of greater than 0.5 mcg/mL or enterococci should receive a similar treatment regimen, as described above.[7]

Patients allergic to β-lactams should receive vancomycin 30 mg/kg/day divided into two doses for 4 to 6 weeks. Although the addition of an aminoglycoside to vancomycin enhances bactericidal activity in vitro, it is unknown whether the addition of an aminoglycoside confers any additional clinical benefit.[7] Assuming the viridans streptococci isolated from A.G. are not resistant to penicillin and he has no other complicating factors, any of the suggested regimens would be appropriate. Because no compelling reason exists to use the 4-week regimens, the 2-week penicillin–aminoglycoside regimen could be the optimal choice. Although A.G. has mild renal impairment, this is most likely secondary to the endocarditis and should improve once adequate antimicrobial therapy has been instituted. A.G. was begun on 12 million units/day of penicillin G, which would be reasonable for his age and mild renal impairment. If nephrotoxicity were a major concern in A.G., penicillin or ceftriaxone alone for 4 weeks is reasonable. If gentamicin is used, A.G.'s renal function should be monitored and the dose should be adjusted appropriately if not using a single daily regimen. Multiple aminoglycoside dosing requires frequent monitoring for signs of toxicity by taking periodic peak and trough aminoglycoside concentrations.

STAPHYLOCOCCUS EPIDERMIDIS: PROSTHETIC VALVE ENDOCARDITIS

Etiology

CASE 66-2

QUESTION 1: F.T., a 65-year-old man, presents with chief complaints of anorexia, fever, chills, and weight loss. His medical history is significant for replacement of his mitral and aortic heart valves (both porcine) 1 month ago for aortic stenosis, mitral regurgitation, and mitral stenosis secondary to rheumatic heart disease. Two weeks later he was readmitted with fever, a right pleural effusion, a pericardial friction rub, and pericarditis. The impression at that time was either postpericardiotomy or Dressler syndrome. F.T. was sent home on anti-inflammatory agents but failed to improve. After continued complaints of anorexia, nausea, chills, and fever to 101°F, he returned to the hospital. On readmission, his physical examination was noteworthy for a systolic ejection murmur at the left sternal border and 3+ pedal edema. Blood cultures were obtained, and routine laboratory studies were performed. His history and clinical presentation were strongly suggestive of PVE. What are the most likely organisms responsible for PVE in F.T.?

PVE is a life-threatening infectious complication of artificial heart valve implantation that accounts for 7% to 25% of cases of IE in developed countries.[36],[37] The prevalence of complications resulting in death has been as high as 20% to 40%.[37] The risk of PVE after surgery is approximately 1% at 12 months and 2% to 3% at 60 months. PVE is categorized as early or late, depending on the onset of clinical manifestations after cardiac surgery.[36],[37] Early PVE occurs within 2 months after surgery and is thought to represent infection acquired during valve placement. It usually is caused by skin organisms that were implanted into the valve annulus (suture site where the valve is attached to cardiac muscle) at the time of surgery.[36],[37] The most common organisms cultured from patients such as F.T. with early PVE are coagulase-negative staphylococci (primarily S. epidermidis [>30%], most of which are resistant to methicillin), followed by S. aureus (20%), and gram-negative bacilli (10%–15%). Miscellaneous organisms, such as diphtheroids and fungi, account for the remainder. In contrast, streptococci are a more common cause of late PVE (>2 months after surgery).[36],[37]

Nosocomial bacteremia and fungemia in a patient with prosthetic heart valves contribute to a significant risk for the development of PVE. One study noted that bacteremia caused by staphylococci and gram-negative bacilli resulted in 55% and 33% of subsequent PVE cases, respectively.[38] Another study observed the development of PVE in 25% (11 of 44) of patients after nosocomial candidemia.[39]

Prophylaxis

CASE 66-2, QUESTION 2: What measures can be taken to prevent early PVE?

The overall frequency of early PVE, despite antibiotic prophylaxis, is 1% to 4%.[40] Complications are severe and include valve dehiscence, acute heart failure, arrhythmias, and outflow obstruction. Although antibiotic prophylaxis before valve surgery (a "clean" procedure) has not been proved to reduce the frequency of early PVE, it is indicated nevertheless because the complications of infection are catastrophic. The antimicrobial regimen used most commonly for cardiac surgery prophylaxis (see Chapter 63, Antimicrobial Prophylaxis for Surgical Procedures) consists of an antistaphylococcal cephalosporin, such as cefazolin, given in the operating room at the time of induction of anesthesia or within 60 minutes before the procedure. Vancomycin could be considered the prophylactic agent of choice for cardiovascular procedures, including prosthetic valve replacement and implantation of prosthetic grafts, in the presence of any of the following: (a) documented penicillin allergy, (b) prior receipt of broad-spectrum antimicrobial therapy and high likelihood of being colonized with cephalosporin-resistant staphylococci or

enterococci, or (c) performance of the procedure in a center experiencing outbreaks or a high endemic rate of surgical infection with methicillin-resistant staphylococci.[41]

Antimicrobial Therapy

CASE 66-2, QUESTION 3: What are the treatment options for F.T.?

As noted earlier, F.T. most likely is infected with coagulase-negative staphylococci. For those rare coagulase-negative staphylococci that remain sensitive to β-lactams (<20%), a penicillinase-resistant penicillin (nafcillin or oxacillin) is the drug of choice (Table 66-4).[42] For the treatment of PVE caused by methicillin-resistant, coagulase-negative staphylococci, vancomycin should be used.[42] Most staphylococci are sensitive to vancomycin at concentrations of 2 mcg/mL or less; however, strains of staphylococci with intermediate susceptibility to vancomycin have emerged.[43],[44] Refer to the IDSA guidelines for vancomycin dosing and drug level monitoring.[19]

The AHA currently recommends the use of triple-drug combination (vancomycin, gentamicin, and rifampin) therapy for the treatment of PVE caused by methicillin-resistant, coagulase-negative staphylococci (MRSE).[7] When isolates of MRSE are resistant to all available aminoglycosides, aminoglycoside treatment should be omitted. A fluoroquinolone active against the isolate may be considered as substitute for the aminoglycoside in the three-drug regimen. In addition to medical therapy, most patients also required valve replacement surgery.[36],[37],[42]

Table 66-4

Treatment of Staphylococcal Endocarditis

Antibiotic	Dosage and Route	Duration
Without Prosthetic Material[a]		
OXACILLIN/METHICILLIN–SUSCEPTIBLE STAPHYLOCOCCI		
NONPENICILLIN-ALLERGIC PATIENTS		
Nafcillin or oxacillin	Adult: 2 g IV every 4 hours	6 weeks
	Pediatric: 150–200 mg/kg/24 hour IV (max: 12 g/24 hour) in four to six equally divided doses	
PENICILLIN-ALLERGIC PATIENTS		
Cefazolin[d]	Adult: 2 g IV every 8 hours	6 weeks
	Pediatric: 100 mg/kg/24 hour IV (max: 6 g/24 hour) in equally divided doses every 8 hours	
Vancomycin[b],[e],[f]	Adult: 30 mg/kg/24 hour IV in two or four equally divided doses (max: 2 g/24 hour unless serum levels monitored)	6 weeks
	Pediatric: 40 mg/kg/24 hour IV in two or four equally	

	divided doses (max: 2 g/24 hour unless serum levels monitored)	
OXACILLIN/METHICILLIN–RESISTANT STAPHYLOCOCCI		
Vancomycin[b,e,f]	Adult: 30 mg/kg/24 hour IV in two or four equally divided doses (max: 2 g/24 hour unless serum levels monitored) Pediatric: 40 mg/kg/24 hour IV in two or four equally divided doses (max: 2 g/24 hour unless serum levels monitored)	6 weeks
With Prosthetic Valve or Other Prosthetic Material[g]		
OXACILLIN/METHICILLIN–RESISTANT STAPHYLOCOCCI		
Vancomycin[b,e,g]	Adult: 30 mg/kg/24 hour IV in two or four equally divided doses (max: 2 g/24 hour unless serum levels monitored) Pediatric: 40 mg/kg/24 h IV in two or four equally divided doses (max: 2 g/24 h unless serum levels monitored)	≥6 weeks
With rifampin[h]	Adult: 300 mg IV/PO every 8 hours	≥6 weeks
	Pediatric: 20 mg/kg/24 hour PO (max: 900 mg/24 hour) in three equally divided doses	
With gentamicin[b,g,i,j]	Adult: 3 mg/kg IV or IM in two or three equally divided doses	2 weeks
	Pediatric: 3 mg/kg IV or IM in three equally divided doses	
OXACILLIN/METHICILLIN–SUSCEPTIBLE STAPHYLOCOCCI		
Nafcillin or oxacillin[k]	Adult: 2 g IV every 4 hours	≥6 weeks
	Pediatric: 150–200 mg/kg/24 hour IV (max: 12 g/24 hour) in four to six equally divided doses	
With rifampin[h]	See prosthetic valve dosing for rifampin above	≥6 weeks
With gentamicin[b,g,i,j]	See prosthetic valve dosing for gentamicin above	2 weeks

[a] Antibiotic doses should be modified appropriately for patients with impaired renal function. Shorter antibiotic courses have been effective in some drug addicts with right-sided endocarditis caused by S. aureus. (See text for comments on the use of daptomycin and rifampin.)

[b] Dosing of aminoglycosides and vancomycin on a milligram per kilogram basis will give higher serum concentrations in obese than in lean patients.

[c] The benefit of additional aminoglycoside has not been established. The risk of toxic reactions because of these agents is increased in patients >65 years of age or those with renal or eighth nerve impairment.

[d] There is potential cross-allergenicity between penicillins and cephalosporins. Cephalosporins should be avoided in patients with immediate-type hypersensitivity to penicillin.

[e] Trough serum concentrations should be obtained within half an hour prior to the next dose and should be in the range of 10 to 15 mcg/mL. (See text for detailed discussion on the need for high trough target of 15 to 20 mcg/mL for strains with reduced susceptibility to vancomycin. Each vancomycin dose should be infused for 1 hour.)

[f] Vancomycin and gentamicin doses must be modified appropriately in patients with renal failure.

[g] Rifampin is recommended therapy for infections caused by coagulase-negative staphylococci. Its use in coagulase-positive staphylococcal infections is controversial. Rifampin increases the amount of warfarin sodium required for antithrombotic therapy.

[h] Serum concentration of gentamicin should be monitored, and the dose should be adjusted to obtain a peak level of approximately 3 mcg/mL.

[i] Use during initial 2 weeks. (See text on alternative aminoglycoside therapy for organisms resistant to gentamicin.)

[j] First-generation cephalosporins or vancomycin should be used in penicillin-allergic patients. Cephalosporins should be avoided in patients with immediate-type hypersensitivity to penicillin and those infected with oxacillin-resistant staphylococci.

IM, intramuscular; IV, intravenous; PO, orally.

Source: Baddour LM et al. Infective endocarditis in adults: diagnosis, antimicrobial therapy, and management of complications. A Scientific Statement for Healthcare Professionals from the American Heart Association (AHA); on behalf of the AHA Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease of the Council on Cardiovascular Disease in the Young, Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and Stroke Council: Endorsed by the Infectious Diseases Society of America. Circulation. 2015;132:1435–1486.

Although alternative agents such as quinupristin/dalfopristin, linezolid, daptomycin, telavancin, ceftaroline, dalbavancin, and oritavancin have shown potent in vitro activity against coagulase-negative staphylococci, clinical experience in the treatment of IE caused by these strains is lacking.[42],[45],[46]

STAPHYLOCOCCUS AUREUS ENDOCARDITIS

Intravenous Drug User Versus Nonuser

CASE 66-3

QUESTION 1: T.J., a 36-year-old human immunodeficiency virus (HIV)-seropositive man with a long history of IV drug abuse, was admitted to the hospital 4 months after being released from the state prison. His chief complaints included fever, night sweats, pleuritic chest pain, shortness of breath, dyspnea on exertion, and fatigue. Physical examination was remarkable for a temperature of 101.2°F, splenomegaly, and a pansystolic ejection murmur at the left sternal border, best heard during inspiration. The chest radiograph revealed diffuse nodular infiltrates. TTE was positive for a small vegetation on the tricuspid valve leaflet. Significant laboratory results included the following:

WBC count, 14,000/μL with 65% polys and 5% bands (SI units, 14 × 10/L with 0.65 polys and 0.05 bands [normal, 3.2–9.8 with 0.54–0.62 polys and 0.03–0.05 bands])
CD4 cell count, 350/μL
Hgb, 13.1 g/dL (SI units, 131 g/L [normal, 140–180])
Hct, 39% (SI units, 0.39 [normal, 0.39–0.49])
ESR, 55 mm/hour (Westergren) [normal, ≤30 mm/minute]

IE was suspected. Blood cultures were obtained, and all six samples were positive for coagulase-positive, gram-positive cocci, later identified as methicillin-sensitive S. aureus (MSSA). How do the clinical presentation and prognosis of endocarditis in the IV drug user differ from that of the nonuser? What impact does HIV infection have on the risk and outcomes of endocarditis in the IV drug user?

The annual incidence of endocarditis among IV drug users is estimated at 1% to 5%; parenteral cocaine addicts have the highest risk.[47] The presentation, pathophysiology, and prognosis of endocarditis in those who acquire the disease secondary to IV drug use differ from those in nonusers.[1],[47],[48] S. aureus is tenfold more likely than other pathogens to cause infection in this population.[7] S. aureus is part of the normal skin flora and is introduced when the illicit drug is injected. The following are differences between addicts and nonaddicts with S. aureus endocarditis: Addicts are significantly younger; they have fewer underlying diseases and more right-sided (tricuspid) involvement (in contrast to the predominance of left-sided disease in nonaddicts); they are less likely to have heart failure or central nervous system complications; and they exhibit fewer signs of peripheral involvement and have a lower incidence of death.[48] Among patients without history of IV drug use, MRSA was involved in one-third of a cohort of 424 patients with definite S. aureus IE. Clinical features that characterized MRSA IE were persistent bacteremia, chronic immunosuppressive therapy, health-care-associated infection, a presumed intravascular device source, and diabetes mellitus.[6]

The prevalence of HIV seropositivity is 40% to 90% among IV drug users with IE.[47],[49] HIV-related immunosuppression may be an independent risk factor for the development of endocarditis.[50]

Antimicrobial Therapy

METHICILLIN-SENSITIVE STAPHYLOCOCCUS AUREUS

CASE 66-3, QUESTION 2: What are the therapeutic options for treating S. aureus endocarditis in T.J.?

The susceptibility of S. aureus to methicillin is the major determinant of which antibiotic is selected to treat T.J.'s endocarditis. T.J. is infected with MSSA. Therapy of choice for methicillin-sensitive strains is a penicillinase-resistant penicillin, such as nafcillin or oxacillin.[7] (Table 66-4). Penicillin G rarely is appropriate because nearly all isolates of S. aureus produce penicillinase. A 6-week course of therapy with high-dose (12 g/day) nafcillin is the therapy of choice.[51],[52] Vancomycin may be less efficacious than nafcillin as an antistaphylococcal agent.[7],[51] IV drug addicts, for the reasons previously identified, have a higher response rate to appropriate therapy compared with nonaddicts. In one study, 31 addicts were successfully treated with 16 days of parenteral therapy followed by 26 days of oral dicloxacillin.[53]

Addicts with uncomplicated right-sided endocarditis caused by MSSA have been treated successfully with a 2-week course of combination therapy with a penicillinase-resistant penicillin and an aminoglycoside.[54–56] In one study, 47 of 50 patients (94%) were cured after treatment with the combination of IV nafcillin (1.5 g every 4 hours) and tobramycin (1 mg/kg every 8 hours) for a total of 2 weeks.

Notably, 2 of 3 patients treated with vancomycin relapsed, resulting in early termination of this arm of study. Thus, vancomycin should not be used to substitute for nafcillin in this regimen. An abbreviated course of treatment can be used in a defined group of IV drug users with right-sided endocarditis. These patients should have the following characteristics: (a) clinical and bacteriologic response within 96 hours of initiation of therapy; (b) no evidence of hemodynamic compromise, metastatic infection, or neurologic or systemic embolic complications at either the initiation or completion of 2 weeks of therapy; (c) no echocardiographically demonstrable vegetations larger than 2 cm^3; (d) not infected with MRSA; and (e) not receiving antibiotics other than penicillinase-resistant penicillins, such as first-generation cephalosporins and glycopeptides.[7],[55] HIV-seropositive patients (CD4 counts >300 × 10^6 cells) with tricuspid involvement included in the above studies also responded favorably to these short-course regimens; thus, a short-course regimen is an option for T.J.[55]

Recent studies suggest that the addition of an aminoglycoside to the treatment regimen does not improve overall response for patients who meet the above criteria for short-course therapy and is associated with increased toxicity. Therefore, the AHA guidelines do not favor the antibiotic combination anymore. Also, all patients receiving the short regimen should be carefully evaluated for evidence of continuing infection or complications before discontinuing therapy at the end of the 2-week treatment course; extension of therapy with a β-lactam agent to at least a 4 to 6-week duration is recommended with any evidence of active disease or complications. Although response to antibiotic therapy has been shown to be similar between asymptomatic HIV-seropositive and HIV-seronegative IV drug users, short-course therapy should be avoided in more immunosuppressed individuals (CD4 cell counts <200 μL) until more definitive outcome data are available in this subgroup.[47]

Oral Regimen

An oral treatment regimen consisting of ciprofloxacin (750 mg every 12 hours) plus rifampin (300 mg every 12 hours) has also been evaluated in addicts with uncomplicated right-sided endocarditis. In one small, noncomparative study, 10 addicts were successfully treated with the combination of ciprofloxacin and rifampin for 4 weeks.[57],[58] Ciprofloxacin was given IV (400 mg every 12 hours) for the first 7 days, followed by oral administration (750 mg every 12 hours) for the remaining 21 days of therapy. Another study prospectively compared the oral regimen with standard parenteral therapy for this subgroup.[58],[59] Patients were randomly assigned to receive 28 days of therapy with oral ciprofloxacin plus rifampin or oxacillin (2 g IV every 4 hours) plus gentamicin (2 mg/kg IV every 8 hours). Vancomycin (1 g IV every 12 hours) was substituted for oxacillin in the penicillin-allergic patients. One of 19 patients in the oral group versus 3 of 25 in the IV group failed treatment; however, approximately half of the study patients in either group had possible endocarditis. Given the small number of patients who completed treatment, therapeutic equivalency between the oral and parenteral regimens will need to be confirmed in larger trials. In addition, emerging quinolone resistance in S. aureus and the compliance and monitoring required of this regimen when administered in the outpatient setting are of concern. Nonetheless, it appears that a 4-week oral regimen with ciprofloxacin and rifampin may be a useful alternative treatment option in addicts with uncomplicated right-sided endocarditis.

Penicillin-Allergic Patients

Treatment of penicillin-allergic patients with S. aureus endocarditis is somewhat controversial. First-generation cephalosporins have been used with some success for the treatment of patients with mild penicillin allergy, but treatment failures with cefazolin are difficult to explain.[60] The stability of cefazolin when exposed to staphylococcal β-lactamase has been proposed as a mechanism for these failures.[61] Notably, staphylococci are capable of producing four penicillinase subtypes, to which the stability of cefazolin varies. These susceptibility differences are apparent on MIC testing only if a larger-than-usual inoculum is used (i.e., $>10^6$ organisms).[61] It is possible that treatment failures with cefazolin may be caused by a combination of the recalcitrant nature of the infection and the instability of cefazolin against a particular subtype of penicillinase produced by the staphylococcal strain, which is not readily detectable via routine MIC testing. For patients with endocarditis caused by S. aureus who have immediate-type hypersensitivity to penicillin, vancomycin or daptomycin may be used. Other treatment options include linezolid and quinupristin/dalfopristin.[62] Selection of agent depends on organism susceptibility, potential of drug–drug interactions, and host predisposition for development of adverse effects.

Combination Therapy

An enhanced response to combination therapy in the experimental animal model of MSSA endocarditis has prompted clinical trials to evaluate whether the addition of gentamicin to nafcillin confers any additional benefit. The combination of nafcillin and gentamicin resulted in more rapid clearing of organisms from the blood, but the response rates were similar to patients treated with nafcillin alone.[51] As expected, the group receiving gentamicin had a higher incidence of nephrotoxicity. Thus, for the routine management of endocarditis caused by MSSA, the addition of a second drug does not appear to offer additional benefit when a penicillinase-resistant penicillin is used and is discouraged due to the lack of clearly established efficacy and aminoglycoside toxicity. (see Case 66-3, Question 2, previous discussion). For patients who remain bacteremic or who fail to improve clinically (usually nonaddicts), imaging studies are often performed to identify metastatic sites of infection (i.e., occult abscess) with possible need for surgical intervention.

METHICILLIN-RESISTANT STAPHYLOCOCCUS AUREUS:

VANCOMYCIN

CASE 66-3, QUESTION 3: How would T.J.'s therapy differ if he were infected with MRSA?

Staphylococcus aureus IE involving methicillin-resistant strains has become increasingly common and accounts for up to 40% of cases.[4],[6] MRSA-infected patients have more chronic comorbid conditions (e.g., diabetes mellitus, hemodialysis dependency) and are more likely to have health-care-associated infection (76% vs. 37%) and an indwelling intravascular catheter or hemodialysis fistula as the presumed source of infection (60% vs. 31%) when compared with patients infected with MSSA.[4],[6] Persistent bacteremia was more common with MRSA IE, occurring in 43% versus 9% of patients infected with MSSA. Of interest, in this study, patients with S. aureus IE from the United States were significantly more likely to be infected with MRSA, to receive vancomycin therapy, and to develop persistent bacteremia.[63]

In 20% of patients with MRSA IE, identifiable health-care contact was absent. MRSA infection is traditionally associated with health-care contact in the nosocomial setting, but is now becoming more prevalent in the community (CA-MRSA).[6] Young and otherwise healthy individuals without the traditional risk factors are infected in the community.[64] CA-MRSA strains are distinct from health-care-associated strains in that most possess a distinct virulence gene encoding for the Panton-Valentine leukocidin (PVL). Expression of this pore-forming toxin that causes severe necrosis in polymorphonuclear neutrophil cells in a rabbit model has been implicated to cause invasive infections, including necrotizing pneumonia and skin abscesses.[65–71] Specifically, CA-MRSA PVL-producing strains causing IE have been reported.[72]

Treatment Options

Vancomycin has been the accepted standard of treatment for MRSA endocarditis. Response to treatment, however, is slower than with semisynthetic penicillins (e.g., nafcillin) for MSSA endocarditis. The mean duration of bacteremia in patients with MSSA endocarditis has been reported to be 3.4 days for nafcillin alone and 2.9 days for the combination of nafcillin and gentamicin.[54] In contrast, the median duration of bacteremia for MRSA endocarditis was 7 days for vancomycin alone. Failure rates of up to 40% have been documented in patients even with right-sided involvement. Of great concern is the emergence of resistant strains of S. aureus after repeated and prolonged exposure to vancomycin therapy.[44],[73]

Either vancomycin or daptomycin at 8 mg/kg IV once daily (up to 12 mg/kg/day) may be used to treat patients with MRSA endocarditis.[63] The AHA recommends daptomycin 8mg/kg/dose. Vancomycin 30 mg/kg/day in two divided doses for a total of 6 weeks is recommended for adults with normal renal function. Vancomycin peak levels are not recommended. Given the emergence of MRSA strains with reduced susceptibility to vancomycin, published guidelines from the Infectious Diseases Society of America recommend a target trough of 15 to 20 mcg/mL[7,63,74] in an attempt to overcome increasing MIC of clinical strains and limited tissue penetration. Measurement of trough serum vancomycin concentrations is typically 30 minutes prior to the fourth dose for patients receiving a dosing interval of every 12 hours. A dosage regimen of vancomycin aimed to achieve an area under the curve-to-MIC ratio of 400 or an unbound trough at 4 to 5 times MIC of the infected strain has been proposed as the optimal pharmacodynamic target.[75–77]

Persistent Bacteremia

CASE 66-3, QUESTION 4: T.J. has been treated with vancomycin 1 g IV every 12 hours for 5 days for his MRSA endocarditis, but does not seem to be clinically improving. His blood cultures are still positive, and his WBC count remains elevated at 12,500/μL with 55% polys and 7% bands. He continues to have a low-grade fever since starting vancomycin. His vancomycin trough level on the second day of therapy was 17 mcg/mL. The infected MRSA strain had a vancomycin MIC of 1.5 mcg/mL as determined by Epsilometer test (Etest). What factors may be contributing to T.J.'s poor response to treatment? What other therapeutic options are available for T.J.?

In a large multinational study of nearly 1,800 patients with definite IE, persistent bacteremia, receipt of vancomycin, and healthcare contact were significantly more common in patients with MRSA IE from the United States compared with those from other geographic regions.[6] The authors speculated that the higher rates of persistent bacteremia in US patients may be attributable in part to the receipt of vancomycin therapy.

Vancomycin MICs against S. aureus have been increasing over the years. At one university medical center, vancomycin MICs were determined by broth microdilution for 6,000 nosocomial MRSA isolates collected during a 5-year period. In the year 2000, 80% of the strains had vancomycin MIC of 0.5 mcg/mL; however, by 2004, 70% of isolates had MICs of 2 mcg/mL.[78] In response to increasing reports of vancomycin failures caused by strains that are in the susceptible range, the vancomycin breakpoint for susceptibility was reduced from 4 to 2 mcg/mL for S. aureus in 2005 per the Clinical and Laboratory Standards Institute.[79,80]

Widespread use of vancomycin has led to the emergence of glycopeptide-intermediate S. aureus (GISA) or heteroresistant GISA (hGISA) strains.[44] Reduced susceptibility to glycopeptides results from an increase in the production of peptidoglycan precursors leading to a thickened cell wall and decreased penetration of glycopeptides into the bacterial cell membrane.[81] In the absence of vancomycin, hGISA strains may revert to glycopeptide susceptibility, making it difficult to detect these strains in vitro. As such, several investigators have found that hGISA strains have an MIC range that overlaps with the currently defined susceptible range and that the prevalence among hospitalized patients is increasing.[82–84] Routine susceptibility testing methods performed in the clinical laboratory are unreliable in detecting MRSA strains with hGISA phenotype.[85] MIC determined by Etest best predicts treatment outcome with vancomycin.[21],[63],[86],[87]

Experts have recommended a target vancomycin trough concentration of 15 to 20 mcg/mL to overcome increasing MIC when treating pneumonia or endocarditis caused by MRSA.[63],[87] A published study of adult infections with MRSA reported that 54% (51 of 95) of clinical isolates had vancomycin MIC of 2 mcg/mL.[20] Notably, invasive infections, such as bacteremia and pneumonia, were linked to higher MIC. Infections caused by those strains were associated with lower end of treatment responses (62% vs. 85%) and increased mortality (24% vs. 10%) compared with strains with MIC of 1 mcg/mL or less, irrespective of attaining a goal trough of 15 to 20 mcg/mL (achieving the goal of 4 to 5 times greater than MIC of an infected strain that has an MIC of 2 mcg/mL). Borderline susceptibility (MIC 2 mcg/mL) and severity of underlying disease were independent predictors of poor treatment response. Many strains demonstrated tolerance to vancomycin as defined by the MBC-to-MIC ratio of 32, and up to 10% exhibited heterogeneous vancomycin-intermediate resistance phenotype (hVISA).[21],[88] Vancomycin monotherapy of hVISA was associated with treatment failure, whereas combination therapy responded favorably.[88] Combination regimens included vancomycin plus rifampin, linezolid, or daptomycin. These findings suggest a role for combination therapy or alternative agents when treating invasive infections caused by MRSA strains with borderline susceptibility. However, the above study was not designed to compare the efficacy of vancomycin monotherapy with combination therapy for the treatment of MRSA infections, and the sample size of patients infected with hVISA in this study was small. Therefore, the role of vancomycin as the treatment

---

of choice for MRSA IE will need to be re-evaluated against other available treatment options.

Despite attaining a pharmacodynamic goal of unbound vancomycin trough level of at least 4 times MIC of the infected strain, T.J. fails to clinically improve and has persistent bacteremia. It is possible that T.J. is infected with a hVISA strain; thus, a change in therapy is warranted.

Daptomycin (Cubicin) is a cyclic lipopeptide that has been approved for treatment of S. aureus bacteremia and right-sided endocarditis. In vivo, it has a wide spectrum of activity against gram-positive bacteria, including S. aureus (including MRSA), Enterococcus faecalis, Enterococcus faecium, streptococci, and most other species of aerobic and anaerobic gram-positive bacteria. It was approved for the treatment of S. aureus bacteremia and endocarditis in a noninferiority study in patients receiving daptomycin or standard therapy consisting of an antistaphylococcal penicillin or vancomycin in addition to low-dose gentamicin.[89] Successful outcome was seen in 46% (41 of 90) of patients who had presumed or definite staphylococcal endocarditis at their baseline diagnosis. Of those, MRSA endocarditis was successfully treated in 42% (15 of 36) of cases. In patients with confirmed uncomplicated and complicated right-sided endocarditis, treatment success was similar between the daptomycin group (8 of 18) and the group receiving standard therapy (7 of 16) at 44%. Microbiologic failure occurred in seven patients in the daptomycin group and in five patients receiving standard therapy. Overall, the most common cause of daptomycin failure was persistent or relapsing infections, accounting for 16% of failures. In contrast, failure of standard therapy was more often the result of treatment-limiting adverse events, accounting for 15% of failures. Increase in the MIC of the infected strain was observed more often in the daptomycin group compared with standard treatment (six in the daptomycin group vs. one patient in the standard therapy group). The use of daptomycin for treatment of left-sided endocarditis is not established because only nine patients were treated and only one had treatment success.

Daptomycin at >8 mg/kg/day for a total duration of 6 weeks should be used for the treatment of endocarditis. Considering its concentration-dependent effects, some recommended higher doses (up to 12 mg/kg/day) which appear to be safe.[63],[90] High-dose daptomycin should be considered in patients who have previously failed vancomycin treatment, who are severely ill, or who are infected with an isolate with elevated vancomycin MICs. Daptomycin should be dosed based on total body weight because obese patients have a larger volume of distribution as well as increased clearance compared with the nonobese population.[91] Creatine kinase levels should be obtained at baseline and weekly to monitor for elevations, and more frequently in patients who may be at risk for developing skeletal muscle dysfunction. High-dose daptomycin at 8 to 12 mg/kg daily should be considered as alternative therapy in T.J. Emergence of cross-resistance to daptomycin after vancomycin exposure has been documented.[92],[93] Similar to a thickened cell wall contributing to decreased susceptibility to vancomycin, the same mechanism is thought to contribute to daptomycin resistance in S. aureus.[94] Therefore, it is important to confirm MRSA susceptibility to daptomycin when used in a patient who had prior vancomycin exposure. Either gentamicin (at 1 mg/kg every 8 hours or 5 mg/kg daily) or rifampin 300 to 450 mg orally (PO) twice daily or both may be used in combination with daptomycin as in vitro synergy has been demonstrated for the combinations.[63] Alternatively, daptomycin 10 mg/kg/dose IV once daily plus linezolid 600 mg PO twice daily may be used, particularly with concomitant pneumonia.[95]

Once daptomycin therapy is initiated, continued monitoring of clinical response and organism susceptibility to daptomycin is warranted because resistance development has been reported during prolonged therapy.[96–99] Daptomycin MIC increase during therapy for S. aureus endocarditis was demonstrated in six patients.[97] Baseline MIC increased from 0.25 to 2 mcg/mL in five isolates and from 0.5 to 4 mcg/mL in one isolate. Five of those six isolates were MRSA.

A potential treatment option for T.J., if his infected MRSA strain demonstrates reduced susceptibility to daptomycin, is the addition of an antistaphylococcal β-lactam agent such as nafcillin or oxacillin to daptomycin based on in vitro synergy studies and few case reports.[100],[101]

Linezolid (Zyvox), an oxazolidinone, is not approved by the US Food and Drug Administration (FDA) for the treatment of endocarditis, but has been used in cases of treatment failures, intolerability to standard therapy, or in infections with multidrug-resistant gram-positive cocci.[102] In a review article that included 33 case reports of endocarditis treated with linezolid, 63.6% of patients had successful outcomes at the end of the follow-up period.[102] MRSA and vancomycin-intermediate S. aureus were the most common pathogens, accounting for 24% and 30% of cases, respectively. Failure with linezolid treatment was documented in seven cases, including four deaths attributed to endocarditis and three owing to persistent positive blood cultures. Thrombocytopenia was the most common adverse effect, occurring in eight of nine patients. In a compassionate-use program, linezolid achieved 50% clinical and microbiologic cure rates at 6-month follow-up in 32 patients with definite IE; MRSA was the causative agent in seven of those patients. The most common adverse events reported in this group were gastrointestinal system effects and thrombocytopenia, each occurring in 15% of patients.[103] The degree of thrombocytopenia associated with linezolid correlates with the extent of drug exposure, as measured by area under the concentration curve and duration of treatment.[104] Of note, treatment failure with linezolid for MRSA endocarditis caused by persistent bacteremia has been described in two patients and in one patient with relapse of infection.[105],[106] Thus, additional efficacy data are needed before linezolid can be recommended for the treatment of IE caused by MRSA. Tedizolid (Sivextro), a novel oxazolidinone, was shown to have only moderate bactericidal activity in vivo in a rabbit model of MRSA endocarditis and was less active than either vancomycin or daptomycin.[107] At this time, tedizolid cannot be recommended as a primary agent in treatment of endocarditis.

ENTEROCOCCAL ENDOCARDITIS

Antimicrobial Therapy

ANTIBIOTIC SYNERGY

CASE 66-4

QUESTION 1: G.S., a 35-year-old woman, has been complaining of anorexia, weight loss, and fever for the past 2 months. Her medical history is significant for an aortic aneurysm with insufficiency that resulted in an aortic valve replacement (porcine) 3 years before admission. Approximately 2 months before admission, G.S. had a cesarean section followed by a tubal ligation. She did not receive antibiotic prophylaxis for either procedure. Physical examination revealed a thin woman (5 foot 0 inches, 48 kg) in no acute distress with evidence of a systolic heart murmur, splinter hemorrhages, and petechiae on her soft palate. Her temperature was 100.2°F. Her WBC count was 14,000/μL (SI unit, 14 × 10/L) with a slight left shift; all other laboratory results were within normal limits. She was not taking any medications, and she has a documented allergy to penicillin (rash, urticaria, and wheezing). The working clinical diagnosis was probable bacterial endocarditis, which was confirmed when four sets of blood cultures grew gram-positive cocci. Antibiotic therapy with gentamicin (50 mg IV every 8 hours) and vancomycin (1,000 mg IV every 12 hours) was begun. Biochemical testing subsequently identified the organism as E. faecalis, highly resistant to streptomycin (MIC >2,000 mcg/mL). Why were two antibiotics prescribed for the treatment of enterococcal endocarditis in G.S.?

Enterococci, unlike streptococci, are inhibited but not killed by penicillin or vancomycin alone.[108,109] The synergistic combination of penicillin (or ampicillin, piperacillin, or vancomycin) with an aminoglycoside is required to produce the desired bactericidal effect.[108,109] One definition of synergy is when a combination of antibiotics lowers the MIC to at least one-fourth the MIC of either drug alone.[110] The mechanism of synergy against enterococci is explained by an increased cellular uptake of the aminoglycoside with agents that inhibit cell wall synthesis (e.g., β-lactams and vancomycin).[111] Because G.S. is allergic to penicillin, vancomycin was prescribed with an aminoglycoside. Relapse rates are unacceptably high if penicillin is used alone for the treatment of enterococcal endocarditis.[7,108,110,111] Numerous in vivo[110,111] and clinical studies have confirmed the in vitro synergy for penicillin in combination with streptomycin or gentamicin for enterococcal endocarditis.[16]

Streptomycin Resistance

As many as 55% of all enterococcal blood isolates are highly resistant to streptomycin (MIC >2,000 mcg/mL), and the combination of streptomycin with penicillin is not synergistic for those isolates. In contrast, gentamicin in combination with penicillin, ampicillin, or vancomycin is synergistic for most blood isolates of enterococci, regardless of their susceptibility to streptomycin.[1,108,112] In addition, ototoxicity in the form of vestibular dysfunction secondary to streptomycin therapy occurs in nearly 30% of patients in the treatment of enterococcal endocarditis and is most often irreversible. High peak concentrations and prolonged drug therapy have been associated with ototoxicity, but laboratory assays for streptomycin levels are not readily available. For these reasons, gentamicin in combination with penicillin (or ampicillin) or vancomycin is recommended by most authorities for the treatment of aminoglycoside-susceptible and, in particular, streptomycin-resistant enterococcal endocarditis, as it was for G.S.[7] Of note, other aminoglycosides cannot be used to substitute for gentamicin or streptomycin because of the uncertain correlation between in vitro synergy and in vivo efficacy.[7] Table 66-5 lists the suggested regimens for the treatment of enterococcal endocarditis.

Gentamicin Resistance

Of the aminoglycosides, gentamicin and streptomycin are often tested with penicillin (or ampicillin) for synergistic bactericidal activity. About 10% to 25% of the clinical isolates of E. faecalis and up to 50% of E. faecium are resistant to gentamicin.[112],[113] Without conclusive data, some groups favor long-term (8–12 weeks) therapy with high-dose penicillin (18–30 million units/day IV in six divided doses) or ampicillin (2–3 g IV every 4 hours) for treatment of resistant enterococci. Ampicillin plus the β-lactamase inhibitor sulbactam (Unasyn) would be substituted for β-lactamase-producing, high-level gentamicin-resistant enterococci. In light of the increasing prevalence of enterococci with high-level aminoglycoside resistance, the potential synergistic interaction between ampicillin or amoxicillin and a third-generation cephalosporin was explored in vitro and in experimental models of IE.[114] A bactericidal synergistic effect was shown between amoxicillin and cefotaxime against 50 strains of E. faecalis. Amoxicillin MIC decreased from 0.25 to 1 mcg/mL to 0.01 to 0.25 mcg/mL for 48 of 50 strains tested.[115] Additionally, Brandt et al.[116] demonstrated a synergistic bactericidal effect for amoxicillin in combination with imipenem against vancomycin–aminoglycoside-resistant E. faecium strains. The authors speculated that saturation of different penicillin-binding proteins by different β-lactam agents may be the underlying mechanism for the synergy observed. In an observational, nonrandomized multi-center study, 159 patients were treated with ampicillin (2 g IV every 4 hours) and ceftriaxone (2 g IV every 12 hours) and 87 were treated with ampicillin and gentamicin.[23] There were no differences in mortality (while on antibiotics and at 3-month follow-up), treatment failure, and relapses. The 2015 AHA guidelines recommend double β-lactam therapy with ampicillin and ceftriaxone as a reasonable option for infections caused by aminoglycoside-resistant E. faecalis strains.

Table 66-5

Therapy for Endocarditis Caused by Enterococci (or Streptococci viridans with an MIC ≥0.5 mcg/mL)

Antibiotic[a,b]	Dose and Route	Duration
Nonpenicillin-Allergic Patient		
Penicillin G	Adult: 18-30 million units/24 hour IV given continuously or in six equally divided doses	4–6 weeks
	Pediatric: 300,000 units/kg/24 hour IV (max: 30 million units/24 hour) given continuously or in four to six equally divided doses	4–6 weeks
With gentamicin[c],[d]	Adult: 1 mg/kg IM or IV every 8 hours	4–6 weeks
	Pediatric: 1 mg/kg IM or IV every 8 hours	4–6

		weeks
Ampicillin	Adult: 12 g/24 hour IV given continuously or in six equally divided doses	4–6 weeks
	Pediatric: 300 mg/kg/24 hour IV (max: 12 g/24 hour) in four to six equally divided doses	4–6 weeks
With gentamicin[c],[d]	See nonpenicillin-allergic dosing for gentamicin above	4–6 weeks
With ceftriaxone	4 g/24 hour IV in two equally divided doses	6 weeks
Penicillin-Allergic Patients[f]		
Vancomycin[e]	Adult: 30 mg/kg/24 hour IV in two equally divided doses (max: 2 g/24 hour unless serum levels monitored)	6 weeks
	Pediatric: 40 mg/kg/24 hour IV in two to three equally divided doses (max: 2 g/24 hour unless serum levels monitored)	6 weeks
With gentamicin[c],[d]	Adult: 1 mg/kg IM or IV (max: 80 mg) every 8 hours	6 weeks
	Pediatric: 1 mg/kg IM or IV (max: 80 mg) every 8 hours	6 weeks

[a] Antibiotic doses should be modified appropriately in patients with impaired renal function.

[b] Enterococci should be tested for high-level resistance (gentamicin: MIC $\geq$500 mcg/mL).

[c] Serum concentration of gentamicin should be monitored and dosage adjusted to obtain a peak level of approximately 3 mcg/mL. (For shorter-course gentamicin therapy for enterococcal endocarditis, see comment in text.)

[d] Dosing of aminoglycosides and vancomycin on a mg/kg basis gives higher serum concentrations in obese than in lean patients.

[e] Trough serum concentrations should be obtained within half an hour of the next dose and should be in the range of 10 to 20 mcg/mL. Each dose should be infused over 1 hour; 6 weeks of vancomycin therapy recommended because of decreased activity against enterococci.

[f] Desensitization should be considered; cephalosporins are not satisfactory alternatives.

IM, intramuscular; IV, intravenous; MIC, minimum inhibitory concentration.

GENTAMICIN

Dosing

CASE 66-4, QUESTION 2: What is the optimal dosage of gentamicin for G.S.?

Because patients with enterococcal endocarditis require prolonged therapy with aminoglycosides, the optimal serum concentration should minimize toxicity without jeopardizing clinical cure. Early in vitro data indicated that the bactericidal activity of gentamicin against enterococci was not significantly different between peak concentrations of 5 and 3 mcg/L; however, the differences between 3 and 1 mcg/mL were significant.[114] Animal models of endocarditis show discordant results in bacterial counts per gram of vegetation in animals on low-dose versus high-dose aminoglycosides.[117],[118] In experimental endocarditis, multiple daily dosing is more effective than single daily dosing in reducing bacterial titers in vegetations.[119–121] In contrast, viridans streptococci endocarditis can be managed with single daily dosing[28] (see Case 66-1, Question 4). Thus, extended-interval dosing of aminoglycosides cannot be recommended for the treatment of enterococcal endocarditis at this time.

The only study comparing high-dose (>3 mg/kg/day) and low-dose (<3 mg/kg/day) gentamicin with penicillin in humans with enterococcal endocarditis evaluated 56 patients during a 12-year period (36 with streptomycin-susceptible and 20 with streptomycin-resistant infections).[122] The relapse rate of patients infected with streptomycin-resistant organisms (n = 20) was not significantly different between the high- and low-dose treatment groups (n = 10 each). Furthermore, patients who received the higher doses of gentamicin experienced a greater prevalence of nephrotoxicity (10 of 10 vs. 2 of 10; $P<0.001$). Mean peak and trough concentrations of gentamicin in patients who received the high doses were 5 and 2.1 mcg/mL, respectively; corresponding levels for patients receiving the low-dose regimen were 3.1 and 1 mcg/mL.

Given the available data, it would be reasonable to start G.S. on a gentamicin dosage of 1 mg/kg every 8 hours (assuming her renal function is normal) and to maintain peak concentrations of 3 to 5 mcg/mL and trough concentrations of less than 1 mcg/mL.

In Combination with Vancomycin

CASE 66-4, QUESTION 3: Why was vancomycin used in combination with gentamicin in G.S.? Is this combination effective against enterococci?

G.S. has a history of penicillin allergy. Most clinicians favor a combination of vancomycin and gentamicin for penicillin-allergic patients with enterococcal endocarditis, although vancomycin plus streptomycin is a suitable alternative.[7],[108],[122] The combination of vancomycin and gentamicin demonstrates bactericidal synergy for about 95% of enterococci strains. In contrast, the vancomycin and streptomycin combination demonstrates bactericidal synergy for about 65% of enterococci. Because G.S. has PVE, she should receive approximately 30 mg/kg/day, or roughly 1.5 g/day (750 mg every 12 hours), of vancomycin in combination with gentamicin (3 mg/kg/day). Serum levels of vancomycin and gentamicin should be monitored as previously discussed.

DURATION OF THERAPY

CASE 66-4, QUESTION 4: How long should G.S. be treated?

Historically, enterococcal endocarditis has been treated with penicillin plus an aminoglycoside for 6 weeks; the overall cure rate with this regimen is about 85%.[7] Four weeks of therapy is probably adequate for most patients with enterococcal endocarditis.[7],[122],[123] One study evaluated the efficacy of a treatment regimen involving shorter-course aminoglycoside therapy (median of 15 days) in combination with a cell wall-active agent for a median of 42 days in patients with PVE and native valve enterococcal endocarditis.[123] Clinical cure was observed in 75 of 93 (81%) patients overall, 78% of patients with PVE, and 82% of patients with native valves. Among those who had a clinical cure, 52% received a β-lactam, 12% received vancomycin, and 36% received a combination of both. Ampicillin was given in 88% of patients receiving a β-lactam. The causative organism was E. faecalis in 78 patients and E. faecium in five patients. Clinical success was also achieved in all eight patients with native valve IE who received either vancomycin (50%), ampicillin (25%), or combination of both (25%) without synergistic aminoglycoside therapy.[123]

Patients with complicated courses should receive 6 weeks of therapy, including patients infected with streptomycin-resistant organisms (such as G.S.), those who have had symptoms for more than 3 months before the initiation of antibiotics, and patients with PVE (such as G.S.).[7],[12] Some clinicians recommend 6 weeks of therapy for all patients in whom the duration of illness cannot be firmly established; this accounts for many patients who present with subacute disease.

CASE 66-4, QUESTION 5: How do enterococci develop resistance to vancomycin? What are the therapeutic implications if G.S. is infected with glycopeptide-resistant enterococci?

GLYCOPEPTIDE RESISTANCE IN ENTEROCOCCI

Vancomycin resistant enterococci (VRE), particularly E. faecium, have emerged in the United States since 1987.[124],[125] The increased use of vancomycin since the mid-1980s has coincided with the increased resistance to this class of compounds. Between 1989 and 1993, the percentage of nosocomial enterococci reported as resistant to vancomycin in the United States rose more than 20-fold, from

---

0.3% to 7.9%.[125] Enterococcal isolates from intensive care units increased even more dramatically, from 0.4% to 13.6%, during that time. Data from the Centers for Disease Control and Prevention National Nosocomial Infections Surveillance (NNIS) system indicate that the rate of increase has slowed down from 31% in 2000 to 12% in 2003.[126],[127] A 12% increase was found in VRE infections in intensive care units between 2003 and the prior 5-year period (1998–2002). Nonetheless, epidemiologic studies conducted by the NNIS system, as well as others, have shown that VRE bacteremia is associated with significantly increased morbidity and mortality.[126],[127]

Although E. faecalis is responsible for 80% to 90% of infections caused by enterococci, E. faecium is more likely to exhibit resistance to glycopeptides compared with E. faecalis; more than 95% of VRE recovered in the United States are E. faecium. Glycopeptide-resistant enterococci synthesize abnormal peptidoglycan precursors that lower the binding affinity of glycopeptides to peptidoglycans.[124] VRE can be broadly classified into three separate phenotypes (A, B, and C) based on three structurally different genes and gene products (e.g., altered ligases).[124] Most (approximately 70%) of resistant enterococci are of the VanA phenotype, which are resistant to high levels of vancomycin (MIC >256 mcg/mL). Expression of resistance is inducible, usually plasmid mediated, and transferable to other organisms via conjugation. The VanB strains exhibit moderate vancomycin resistance (MIC 16–64 mcg/mL), and the VanC strains are the least resistant (vancomycin MIC 8–16 mcg/mL, because of chromosomal-mediated constitutive expression (i.e., not inducible as are VanA and VanB); however, VanC isolates usually are associated with the much less common Enterococcus gallinarum and Enterococcus casseliflavus infections.

Vancomycin, and also extended-spectrum cephalosporins and drugs with potent antianaerobic activity are risk factors for VRE.[124]

Few therapeutic alternatives exist for VRE, and synergistic combinations are required for bactericidal activity and clinical cure in endocarditis. Consequently, the treatment of choice is unknown. As a result, practitioners must make decisions using the available data from in vitro synergy studies, experimental models of endocarditis, and scattered case reports. Of additional concern, glycopeptide-resistant isolates often exhibit concomitant high-level resistance to aminoglycosides and β-lactams (e.g., ampicillin, penicillin) secondary to either β-lactamase production or alteration in the target penicillin-binding proteins.

Several antibiotic combinations appear promising in vitro and in preliminary animal models of endocarditis, but few data are currently available in humans. Those combinations include high-dose ampicillin (20 g/day) or ampicillin/sulbactam plus an aminoglycoside; vancomycin, penicillin or ceftriaxone, and gentamicin; ampicillin and imipenem; ciprofloxacin and ampicillin; and ciprofloxacin, rifampin, and gentamicin.

Streptogramin and Oxazolidinone

Quinupristin/dalfopristin (Synercid) and linezolid (Zyvox) are two agents with activity and proven efficacy against some infections caused by VRE. Quinupristin/dalfopristin received accelerated approval by the FDA in late 1999 specifically for the treatment of vancomycin-resistant E. faecium bacteremia.

However, in 2010, with other therapies available for the treatment of VRE, this FDA-labeled indication was removed. The fixed product is generally bactericidal against susceptible streptococci and staphylococci (including methicillin-resistant strains), but it is bacteriostatic against E. faecium. Specifically, E. faecalis is not susceptible to the agent because of the presence of an efflux[128] pump conferring resistance to dalfopristin.

Linezolid has bacteriostatic activity against enterococci, including vancomycin-resistant E. faecium and E. faecalis. It is also active against other gram-positive cocci, including Streptococcus pneumoniae and methicillin-resistant staphylococci.[129] Vancomycin-resistant E. faecium isolates resistant to linezolid have been isolated.[130],[131] Treatment experience with linezolid under the compassionate-use protocol reported clinical and microbiologic cure rates of 50% at 6-month follow-up for patients with endocarditis. Vancomycin-resistant E. faecium was the causative organism for 19 of the 32 patients treated.[103] Common adverse effects associated with linezolid include nausea, headache, diarrhea, rash, and altered taste. Of greater concern is its potential to cause myelosuppression. Thrombocytopenia, leukopenia, anemia, and pancytopenia have all been reported. Up to 30% of patients treated experience thrombocytopenia (platelet counts <100,000 platelets/μL).[129] Linezolid given orally or via enteral feedings is completely bioavailable.[132] A dosage of 600 mg twice daily is recommended for adults.

Daptomycin

Daptomycin is active against enterococci in vitro, with a MIC range of 0.25 to 4 mcg/mL and MIC_{90} of 4 mcg/mL for 219 vancomycin-resistant E. faecium isolates from the United States. For 40 vancomycin-resistant E. faecalis isolates, the MIC range is 0.015 to 2 mcg/mL, with a MIC_{90} of 2 mcg/mL. Of concern is the emergence of daptomycin resistance during therapy for VRE infections.[133],[134] In a case report of a patient with vancomycin-resistant E. faecium pyelonephritis, the initial isolate had an MIC of 2 mcg/mL; however, after 17 days of treatment, a blood culture yielded growth of vancomycin-resistant E. faecium with an MIC increase to 32 mcg/mL.[135] Clinical experience with daptomycin for vancomycin-resistant E. faecium endocarditis is limited, and treatment failure has been reported.[136] If daptomycin therapy is chosen, a dose of 10–12 mg/kg/day is recommended.[7]

FUNGAL ENDOCARDITIS CAUSED BY CANDIDA ALBICANS

Prognosis and Treatment

CASE 66-5

QUESTION 1: B.G., a 35-year-old male heroin addict, was admitted to the hospital with chief complaints of pleuritic chest pain and dyspnea on exertion. Physical examination revealed a cachectic man with a temperature of 104°F, a diastolic regurgitant heart murmur heard loudest during inspiration, splenomegaly, and pharyngeal petechiae. Funduscopic examination was noncontributory. On the chest radiograph, several pulmonary infiltrates with cavitation were evident. UA was significant for microscopic hematuria and RBC casts. A TEE demonstrated vegetations on both the tricuspid and aortic heart valves. B.G. had evidence of moderate heart failure, although his hemodynamic status at that time was "stable." Six sets of blood cultures were drawn over the course of 2 days, and broad-spectrum empiric coverage consisting of vancomycin, gentamicin, and ceftazidime was initiated. Two days later, two of the cultures grew Candida albicans, and a diagnosis of fungal endocarditis was established. What is B.G.'s prognosis, and how should his fungal endocarditis be treated?

Fungal endocarditis is a rare but life-threatening infection that is difficult to diagnose and even more difficult to treat.[1] Most cases are caused by Candida and Aspergillus species. Fungal endocarditis occurs primarily in IV drug users, patients with prosthetic heart valves, immunocompromised patients, those with IV catheters, or patients receiving broad-spectrum antibiotics.[137–140]

Management of fungal endocarditis generally requires early valve replacement and aggressive fungicidal therapy with amphotericin deoxycholate B 0.6 to 1 mg/kg/day with or without 5-flucytosine (5-FC) 25 mg/kg orally QID. If B.G. had poor renal function, liposomal formulations of amphotericin B 3 to 5 mg/kg daily can be used as an alternative.[141]

These antifungal agents should be prescribed for B.G., and his broad-spectrum antibiotic should be discontinued. B.G.'s clinical presentation and chest radiograph indicate that fragments of vegetation have already embolized to his lungs and possibly to other vital organs (e.g., spleen, kidneys). Because of the morbidity and mortality associated with major emboli and valvular insufficiency, B.G. should undergo surgery within 48 to 72 hours after antifungal therapy has been initiated. The prognosis for B.G. is dismal even with proper medical and surgical treatment. In a series analyzing 270 cases of fungal IE occurring during a 30-year period, mortality for those who received combined medical and surgical management was 45%, compared with 64% for those who received antifungal therapy alone.[137] Despite initial response to treatment, the rate of relapse is high (30%–40%), and relapse can occur up to 9 years after the initial episode of infection.[137–140] Most deaths in IV drug users with endocarditis are secondary to heart failure, a finding already evident in B.G.[1] In addition, replacement of a heart valve for fungal endocarditis in a heroin addict carries a significant risk of late morbidity and mortality.[137]

COMBINATION THERAPY WITH 5-FLUCYTOSINE AND AMPHOTERICIN

B

CASE 66-5, QUESTION 2: Why is it important to treat B.G.'s fungal endocarditis with the combination of 5-FC and conventional or lipid-based amphotericin B? What is the optimal duration of therapy?

The poor prognosis associated with fungal endocarditis warrants the administration of 5-FC in combination with amphotericin B, despite its potential for causing bone marrow suppression and hepatotoxicity.[137] The vegetations from B.G.'s tricuspid or aortic heart valves already have broken off and caused pulmonary cavitation and possibly splenomegaly. His clinical presentation is consistent with a potentially fatal outcome; therefore, his blood isolates should be tested for in vitro susceptibility to amphotericin, 5-FC, and azoles. Fungi resistant to 5-FC alone may still be susceptible to the synergistic effect of the 5-FC–amphotericin B combination.[142] If the organism is resistant to 5-FC, in vitro synergy between these two antifungals should be performed or therapy with an echinocandin should be considered.

The optimal dose and duration of antifungal therapy for fungal endocarditis have not been determined by clinical studies; however, postoperative treatment with amphotericin B and 5-FC (if it has in vitro activity) for a minimum of 6 weeks (total dose, 1.5–3 g of amphotericin B) is recommended and is supported by the poor penetration of amphotericin B into heart valve tissue.[143] In patients with fungal PVE, some experts advocate secondary prophylaxis for a minimum of 2 years or lifelong suppressive treatment with an oral antifungal agent for nonsurgical candidates in light of the high rates of relapse.[1],[137],[139],[142–145]

Nephrotoxicity caused by amphotericin B is often a serious dose-limiting factor to completion of therapy, particularly in patients who require a prolonged treatment course. Renal dysfunction secondary to the conventional formulation of amphotericin B may stabilize or improve with the switch to lipid-formulated amphotericin B products (i.e., Abelcet, AmBisome).[146] The efficacy of the new formulations in the treatment of endocarditis has been demonstrated only in anecdotal reports.[137],[139],[142],[143],[147] Alternative antifungal agents, including echinocandins and azoles, are potential options in patients who experience significant renal toxicities.

ALTERNATIVE ANTIFUNGALS

CASE 66-5, QUESTION 3: If B.G. experiences significant toxicities because of prolonged combination treatment with amphotericin and 5-FC, what alternative antifungal agent(s) can be used to treat his fungal endocarditis?

Fluconazole (Diflucan) is a triazole compound active against Candida species, particularly C. albicans and Candida parapsilosis. It also has a favorable toxicity profile compared with amphotericin and 5-FC.[148]

Successful experience with fluconazole treatment of fungal endocarditis in humans has been described in only a few case reports.[149–152] Patients with various Candida species were treated with 200 to 600 mg of fluconazole daily for 45 days to 6 months or until death. Fluconazole therapy reduced or completely removed all cardiac vegetations and resolved clinical symptoms. Because of the lack of adequate clinical experience, however, the use of fluconazole in treating fungal endocarditis cannot be advocated except in patients who require lifelong therapy because of the following situations: (a) The patient is a poor surgical candidate, (b) the patient has relapsed at least once since the initial infection episode, or (c) the patient has PVE.

Another alternative treatment option is the echinocandins which are fungicidal against most Candida species, including those in biofilms. A limited but growing body of literature primarily in case reports describes the successful outcomes with use of the echinocandins in Candida IE. Echinocandin-based regimens including caspofungin, micafungin, and anidulafungin were found to be as effective and to have similar mortality rate as amphotericin-based therapies based on a subgroup analysis of 25 patients in a prospective international cohort of patients with Candida IE.[153]

GRAM-NEGATIVE BACILLARY ENDOCARDITIS CAUSED BY PSEUDOMONAS AERUGINOSA

Prevalence

CASE 66-5, QUESTION 4: Fourteen months after completing his course of antifungal therapy, B.G. was readmitted to the hospital with a 48-hour history of fever, shaking chills, rigors, and night sweats. His vital signs at that time were blood pressure, 100/60 mm Hg; pulse, 120 beats/minute; respirations, 24/minute; and temperature, 103.7°F. A new-onset systolic murmur was noted on auscultation. Two-dimensional echocardiography revealed two small vegetations on the prosthetic valve. Empiric therapy consisting of amphotericin B, 5-FC, vancomycin, and gentamicin was initiated. Three blood cultures drawn on the day of admission were positive for P. aeruginosa with the following antibiotic susceptibilities: gentamicin (8 mcg/mL), tobramycin (2 mcg/mL), piperacillin–tazobactam (16 mcg/mL), and ceftazidime (2 mcg/mL). A presumptive diagnosis of PVE caused by P. aeruginosa was made. Why was the finding of Pseudomonas expected in B.G.?

The prevalence of endocarditis caused by gram-negative organisms has increased significantly over the years, especially in IV drug users such as B.G. and patients with prosthetic heart valves. Gram-negative organisms are responsible for about 15% to 20% of endocarditis cases in these populations.[43] Most gram-negative endocarditis cases are caused by Pseudomonas species, S. marcescens, and Enterobacter species, although numerous other gram-negative organisms have been known to cause endocarditis.[43],[128],[154–157] In narcotic addicts with gram-negative endocarditis, the tricuspid, aortic, and mitral valves are involved in 50%, 45%, and 40% of cases, respectively.[128]

Antimicrobial Therapy

CASE 66-5, QUESTION 5: How should B.G.'s gram-negative endocarditis be treated and monitored?

The previous empirical antimicrobials should be discontinued because P. aeruginosa has been cultured from B.G.'s blood. A bactericidal combination of antibiotics usually is required to provide in vivo synergy and to prevent resistant subpopulations from emerging during therapy.[1],[158] Endocarditis caused by P. aeruginosa (as in B.G.) should be treated for at least 6 weeks with a combination of an aminoglycoside and an antipseudomonal penicillin (piperacillin–tazobactam) or cephalosporin (ceftazidime).[1],[156],[159–161] The combination of an antipseudomonal penicillin and an aminoglycoside is synergistic in vitro and in the rabbit model of P. aeruginosa endocarditis,[160],[161] and clinical experience has confirmed this finding in IV drug users. Combination therapy with high dosages of tobramycin or gentamicin (8 mg/kg/day) has been associated with a significantly higher cure rate and lower mortality rate compared with an older, low-dose regimen (2.5–5 mg/kg/day).[43],[156],[159] B.G., therefore, should be treated with ceftazidime (2 g IV every 8 hours) with concurrent high-dose tobramycin (3 mg/kg IV every 8 hours). Aminoglycosides (tobramycin or gentamicin) should be dosed to produce peak and trough serum concentrations of 15 to 20 mcg/mL and less than 2 mcg/mL, respectively, to ensure maximum efficacy.[1] Finally, the infected valve should be surgically excised for the reasons previously discussed.

Other antibiotics including imipenem, meropenem, aztreonam, cefepime, and ciprofloxacin are active against many of the gram-negative organisms causing endocarditis. Clinical data regarding their use in the treatment of endocarditis are very limited, however.[162–165] Ceftolozane/tazobactam (Zerbaxa) is a novel cephalosporin combination β-lactamase inhibitor with enhanced activity against Pseudomonas and may be an alternative for treatment of multi-drug resistant Pseudomonas infections. Its efficacy for the treatment of endocarditis is still being investigated.

CULTURE-NEGATIVE ENDOCARDITIS

CASE 66-5, QUESTION 6: B.G.'s history, clinical presentation, and imaging studies are strongly suggestive of IE. If his blood cultures had been negative after 48 hours of incubation, the working diagnosis would have been culture-negative endocarditis. What are the possible reasons for culture-negative endocarditis, and what measures should be taken to establish a microbiologic etiology?

The proportion of patients with culture-negative endocarditis has diminished considerably, presumably as a result of improved microbiologic culture techniques. Negative blood cultures are present in only 5% to 7% of patients who meet strict criteria for the diagnosis of IE and have not recently received antibiotics.[166] The prior administration of antimicrobials is thought to account for most cases of culture-negative endocarditis.[166] B.G.'s blood cultures may remain negative for several days to weeks if he has taken antibiotics recently.

Slow-growing and fastidious organisms, such as gram-negative bacilli in the Haemophilus–Actinobacillus–Cardiobacterium–Eikenella–Kingella group (HACEK), Brucella, Coxiella, chlamydiae, strict anaerobes, and fungi, should be pursued in culture-negative patients. This usually is accomplished by the use of special culture media or by obtaining appropriate serologic acute and convalescent titers. Blood cultures should be saved for at least 3 weeks to detect slow-growing organisms.[166] Of note, previously NVS has been the cause of most of the cases of endocarditis diagnosed as culture-negative, initially because of its requirement for the addition of vitamin B_6 (pyridoxal HCl) to the culture media for laboratory growth; however, laboratory identification is no longer a significant problem with current culture media and laboratory techniques.[9]

Empiric Therapy

CASE 66-5, QUESTION 7: The causative organism remains unidentified. Recommend an antimicrobial regimen for the empiric treatment of B.G.'s presumed culture-negative endocarditis.

In the hemodynamically stable patient, antibiotic therapy should be withheld until positive blood cultures are obtained.[1] Based on B.G.'s clinical presentation and echocardiographic findings, empiric antibiotics should be initiated as soon as necessary cultures have been collected. Because staphylococci (often MRSA) and gram-negative bacilli account for most cases of endocarditis in the narcotic addict with a prosthetic heart valve, B.G. should be started on a four-drug regimen: vancomycin targeting a trough of 15 to 20 mcg/mL, gentamicin targeting a peak of 3 to 4 mcg/mL, cefepime 2 g IV every 8 hours, and rifampin 300 mg IV/PO every 8 hours.[7] Because B.G. may be experiencing a relapse caused by C. albicans, the addition of amphotericin B and 5-FC would be appropriate. Depending on the gram-negative pathogens common to the region and their anticipated susceptibilities, a third-generation cephalosporin (ceftriaxone or ceftazidime) or piperacillin–tazobactam could be used. The combination of an aminoglycoside and piperacillin–tazobactam also will provide coverage for enterococci.

B.G.'s clinical status and the positive echocardiogram indicate that early surgical valve excision and replacement are necessary. Cultures obtained from the excised valve may allow for identification of the causative organism and subsequent alteration of his antimicrobial regimen depending on susceptibilities.

PROPHYLACTIC THERAPY

Rationale and Recommendations

CASE 66-6

QUESTION 1: B.B., a 74-year-old man with poor dentition, is scheduled to have all of his remaining teeth extracted for subsequent fitting of dentures. His medical history is significant for numerous infections of the oral cavity and prosthetic valve replacement 2 years ago. His only current medications are oral digoxin (Lanoxin) 0.125 mg/day and furosemide (Lasix) 40 mg every morning. What is the rationale for antibiotic prophylaxis?

Because IE is associated with significant mortality and long-term morbidity, prevention in susceptible patients is of paramount importance.[1] Estimates are, however, that less than 10% of all cases are theoretically preventable.[167] The incidence of endocarditis in patients undergoing procedures known to cause significant bacteremia, even without antibiotic prophylaxis, is low. In addition, endocarditis may develop after the administration of seemingly appropriate chemoprophylaxis. Therefore, it is not surprising that the efficacy of prophylaxis has never been established through placebo-controlled clinical trials. Approximately 6,000 patients would be necessary to demonstrate a statistical difference (if one exists) between untreated controls and a group receiving prophylaxis.[168]

Without conclusive clinical data from prospective trials, recommendations for antibiotic prophylaxis have been based largely on in vitro susceptibility data, evaluation of antibiotic regimens using animal models of endocarditis, and anecdotal experiences.[168]

Prophylactic antibiotics are thought to provide protection by decreasing the number of organisms reaching the damaged heart valve from a primary source. Thus, antibiotics theoretically prevent bacterial multiplication on the valve and interfere with bacterial adherence to the cardiac lesion.[168]

The 2007 AHA recommendations for antibiotic prophylaxis before common medical procedures are outlined in Table 66-6.[168] Compared with the previous (1997) guideline, the current guidelines only recommend the use of prophylaxis in patients with specific cardiac conditions (associated with the highest risk of adverse outcomes from endocarditis) who are undergoing only dental or respiratory tract procedures. The use of prophylaxis for patients undergoing genitourinary or gastrointestinal procedures is not recommended because of a continuing lack of evidence to support efficacy.

DENTAL AND UPPER RESPIRATORY TRACT PROCEDURES

Analysis of published data shows that viridans streptococcal bacteremia can result from any procedure that involves the manipulation of the gingival tissue or the periapical region of the teeth or perforation of the oral mucosa. Placement or removal of prosthodontic or orthodontic appliances, adjustment of orthodontic appliances, taking dental radiographs, bleeding from trauma to the lips or oral mucosa, and instantaneous shedding of deciduous teeth do not require chemoprophylaxis. Endotracheal intubation also does not require prophylactic therapy.

Antimicrobial prophylaxis should be directed against the viridans group of streptococci because these organisms are the most common cause of endocarditis after dental procedures. Invasive surgical procedures involving the upper respiratory tract, such as incision or biopsy of the respiratory mucosa (e.g., tonsillectomy, adenoidectomy), can cause transient bacteremia with organisms that have similar antibiotic susceptibilities to those that occur after dental procedures; therefore, the same regimens are suggested. Prophylaxis is not recommended for bronchoscopies unless the procedure involves incision of the respiratory mucosa. Amoxicillin is currently recommended for oral prophylaxis in susceptible persons having dental or upper respiratory tract surgery. Oral clindamycin, clarithromycin, or azithromycin is recommended for patients with immediate-type hypersensitivity reaction to penicillins. Only patients with outlined cardiac conditions should receive prophylactic antibiotics.

Table 66-6

Cardiac Conditions for Which Prophylaxis is Recommended

Cardiac Conditions

Prophylaxis Recommended

- Prosthetic cardiac valves
- Previous bacterial endocarditis
- Congenital heart disease
  - Unrepaired cyanotic CHD, including palliative shunts and conduits
  - Completely repaired congenital heart defect with prosthetic material device during the first 6 months after the procedure
  - Repaired CHD with residual defects at or adjacent to the site of the prosthetic device or patch
  - Mitral valve prolapse with valvular regurgitation and/or thickened leaflets
- Cardiac transplantation recipients who develop cardiac valvulopathy

CHD, congenital heart disease.

Source: Wilson W et al. Prevention of infective endocarditis: guidelines from the American Heart Association: a guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care an Outcomes Research Interdisciplinary Working Group. American Heart Association [published correction appears in Circulation. 2007;116:e376]. Circulation. 2007;116:1736.

Most cases of endocarditis caused by bacterial flora from the mouth do not follow dental procedures but rather are the result of poor oral hygiene. The cumulative exposure to random bacteremias from daily oral activities is estimated to be 5,730 minutes during a 1-month period compared with only 6 to 30 minutes for a dental procedure. Furthermore, it is estimated that the cumulative exposure to bacteremia from routine daily activities may be up to 5.6 million times greater than a single tooth extraction.[168] Based on the study results, concerns for antimicrobial resistance, and cost, changes to restrict the use of antibiotic prophylaxis before dental procedures to the highest-risk patients may be expected with future guidelines issued by the AHA.

Indications and Choice of Agent

CASE 66-6, QUESTION 2: Is prophylactic antibiotic therapy indicated for B.B.? If so, which antibiotic(s) should be used?

Based on the current recommendations, B.B. is a candidate for antibiotic prophylaxis. Presence of a prosthetic aortic valve while undergoing multiple tooth extractions places him at risk for experiencing endocarditis. He also is scheduled to have all of his remaining teeth extracted, a procedure likely to result in bacteremia. According to Table 66-7, B.B. should receive a single 2-g oral dose of amoxicillin 1 hour before the procedure.

Table 66-7

Endocarditis Prophylaxis Regimen Indicated for Patients with Cardiac Conditions

Drug[a]	**Dose**
Dental or upper respiratory tract procedures	Single dose 30–60 minutes before procedure
Standard Regimen	
Amoxicillin	Adult: 2 g
	Pediatric: 50 mg/kg
Allergic to Penicillin or Ampicillin	
Clindamycin	Adult: 600 mg
	Pediatric: 20 mg/kg
Cephalexin[b],[c]	Adult: 2 g
	Pediatric: 50 mg/kg
Azithromycin or clarithromycin	Adult: 500 mg
	Pediatric: 15 mg/kg

Unable to Take Oral Medications	
Ampicillin	Adult: 2 g IM or IV
	Pediatric: 50 mg/kg IM or IV
Allergic to Penicillin or Ampicillin	
Clindamycin	Adult: 600 mg IM or IV
	Pediatric: 20 mg/kg IV
Cefazolin[b]	Adult: 1 g IM or IV
	Pediatric: 50 mg/kg IM or IV

[a] See Table 66-6.

[b] Cephalosporins should not be used in individuals with immediate-type hypersensitivity reaction (e.g., urticaria, angioedema, or anaphylaxis) to penicillins or ampicillin.

[c] Other first- or second-generation oral cephalosporins in equivalent adult or pediatric dose.

IM, intramuscular; IV, intravenous.

Respiratory Tract Infections

Jason Cross, Evan Horton, and Dinesh Yogaratnam

	CORE PRINCIPLES	CHAPTER CASES
	ACUTE BRONCHITIS	
1	Acute bronchitis is a commonly encountered clinical diagnosis exhibited by cough for more than 5 days and generally does not require treatment with antimicrobial agents.	**Case 67-1 (Questions 1 and 3)**
	ACUTE EXACERBATION OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE	
1	Antibiotics should be provided to patients with acute exacerbations of chronic obstructive pulmonary disease (AECOPD) if three primary symptoms (increased dyspnea, increased sputum volume, and increased sputum purulence) are present, if two primary symptoms are present and increased sputum purulence is one of the symptoms, or with required mechanical ventilation.	**Case 67-2 (Question 4)**
2	Hospitalized patients with AECOPD should both be optimally treated, and their COPD management be assessed to decrease the likelihood of readmission. Baseline COPD medications should be examined and adjusted based on disease severity. Additionally, an assessment of patients' understanding of the role of medications (maintenance therapy vs. rescue medications), ability to use inhalers correctly, access to prescribed medications, and discussions regarding pulmonary rehabilitation should take place. Consideration for pharmacologic venous thromboembolism prophylaxis should also be made in this high-risk population.	**Case 67-2 (Question 6)**
3	Vaccinations to prevent influenza and Streptococcus pneumoniae in patients with COPD or previous pneumonia reduce disease-associated morbidity.	**Case 67-2 (Question 7)**
	COMMUNITY-ACQUIRED PNEUMONIA	
1	The first decision after a diagnosis of community-acquired pneumonia (CAP) is to determine the need for hospitalization. Several predictive rules including the pneumonia severity index (PSI) and CURB-65 (confusion, uremia, increased respiratory rate, low blood pressure, and age ≥65 years) have been developed to facilitate site-of-care decision making.	**Case 67-3 (Question 2)**

2	The most frequently isolated bacterial pathogen causing CAP, regardless of epidemiologic factors and severity of illness, is S. pneumoniae.	**Case 67-3 (Question 4)**
3	The most important consideration when selecting empiric therapy is to identify patients at risk for infection with drug-resistant S. pneumoniae (DRSP).	**Case 67-3 (Question 5)**
4	Patients who continue to have a positive laboratory test result for influenza more than 48 hours after the onset of illness are at high risk of requiring hospitalization, or who are not improving should also be treated.	**Case 67-4 (Question 2)**

HOSPITAL-ACQUIRED, VENTILATOR-ASSOCIATED, AND HEALTH CARE–ASSOCIATED PNEUMONIA

1	Hospital-acquired pneumonia (HAP) is defined as pneumonia that occurs at least 48 hours after hospital admission. Ventilator-associated pneumonia (VAP) refers to pneumonia that arises 48 to 72 hours after endotracheal intubation. Health care–associated pneumonia (HCAP) is diagnosed in any patient who has been hospitalized in an acute-care hospital for 2 or more days within 90 days of infection; resided in a nursing home or long-term care facility; received intravenous antibiotic therapy, chemotherapy, or wound care within the past 30 days of the current infection; lived in close contact with a person with a multidrug-resistant (MDR) pathogen; or attended a hospital or hemodialysis clinic.	**Case 67-5 (Question 1)**
2	The major difference in the bacteriology between CAP and HAP/HCAP/VAP is a shift to gram-negative pathogens, MDR pathogens, and methicillin-resistant Staphylococcus aureus (MRSA) in HAP/HCAP/VAP.	**Case 67-5 (Question 1)**
3	Risk factors for pneumonia caused by MDR pathogens include antimicrobial therapy in the previous 90 days, current hospitalization of 5 days or more, immunosuppressive disease or therapy, or any risk factor for HCAP.	**Case 67-5 (Question 1)**
4	Patients with early-onset pneumonia (<5 days) and no MDR risk factors can be treated with a single agent, including a non-antipseudomonal third-generation cephalosporin or ertapenem, ampicillin/sulbactam, or an antipneumococcal fluoroquinolone. Empiric therapy in those with late-onset pneumonia (≥5 days) or MDR risk factors should include a combination of antibiotics active against Pseudomonas aeruginosa. This regimen usually includes an antipseudomonal β-lactam, plus either an aminoglycoside or ciprofloxacin/levofloxacin. Vancomycin or linezolid should be added if MRSA risk factors are present or if there is a high incidence at the health care facility.	**Case 67-6 (Question 2)**

ACUTE BRONCHITIS

Definition and Incidence

Acute bronchitis (AB) is defined as an acute, self-limiting respiratory illness of the upper bronchi accompanied by cough for more than 5 days that can last up to 3 weeks.[1–3] AB may be associated with or without purulent sputum production, and fever is rare.[2] Patients can be diagnosed with AB when there is no evidence of pneumonia and when acute asthma, an acute exacerbation of chronic obstructive pulmonary disease (AECOPD), or the common cold have been ruled out as the cause of cough.[3] While the true incidence of AB is unknown, it is considered to be one of the most common conditions encountered in clinical practice, accounting for more than 6.7 million outpatient visits per year.[4]

Pathophysiology and Epidemiology

AB is characterized by the inflammatory response to infection in the epithelium of the bronchi. Further progression of this inflammation leads to thickening of the tracheal mucosa.[1],[2] Sloughing of cells from the tracheobronchial epithelium and inflammatory mediators causes bronchospasm and reduced forced expiratory volume in 1 second (FEV_1) that usually improves after 5 weeks. Spread of pathogen and inflammatory response correlate with patient symptoms. Although bacteria can be isolated from sputum, bacterial invasion of the bronchial tree rarely occurs, and the role of bacterial pathogens in AB is limited.[5] The vast majority of cases of AB are presumed to be caused by viruses.[2],[5–7]

Clinical Presentation

Cough lasting for more than 5 days is the hallmark sign of AB. Although the illness is self-limited, cough can last for up to 3 weeks (typical duration 10–20 days). Sputum production occurs in up to 50% of cases, but it does not indicate bacterial infection.[3] Fever is unusual in most cases; when present, it should prompt investigation for influenza (during appropriate seasons) or for pneumonia (if other clinical signs are present).

Overview of Drug Therapy

Antimicrobials do not significantly reduce symptoms of AB, and their use increases the risk of adverse drug events and antimicrobial resistence.[8] Expert guidelines in the United States and abroad recommend against the use of antimicrobial agents for the treatment of AB.[3,6,7,9] Despite the evidence refuting their use, greater than 70% of AB cases are treated with antibiotics in the United States. Furthermore, the agents used for AB are increasingly broad-spectrum drugs, further exacerbating bacterial resistance pressure.[10] Non-antimicrobial treatment considerations include bronchodilators or antitussives depending on symptoms, even though evidence to support the use of many of these modalities is limited.[3,11,12]

Clinical Presentation

CASE 67-1

QUESTION 1: A.R. is a 50-year-old man presenting with a chief complaint of cough. His symptoms have persisted for 8 days, and he now produces yellow sputum with each cough. He has had no recent illnesses; however, his 14-year-old son in high school has experienced recent mild colds. A.R. denies nausea, vomiting, or fever and chills. A review of systems reveals fatigue and difficulty sleeping because of cough. Past medical history includes hypertension managed with lisinopril and hyperlipidemia for which he takes atorvastatin. He also takes low-dose aspirin for stroke prevention. Vital signs indicate a temperature of 37.1°C, heart rate of 70 beats/minute, blood pressure of 130/70 mm Hg, and respiratory rate of 18 breaths/minute with accompanying oxygen saturation of 98% on room air. His physical examination is positive for coarse breath sounds that clear with coughing, but it is otherwise normal. What signs and symptoms in A.R. are consistent with AB?

Persistent cough in the absence of other symptoms including fever or myalgia is typical with AB.[3] Cough can last up to 3 weeks and is usually self-limited. The typical duration of symptoms in AB is 5 to 14 days.[2] Pneumonia must be ruled out; however, normal oxygen saturation and lack of focal signs on pulmonary physical examination makes this diagnosis less likely. Sputum production is common, although not present in all cases of AB. Symptoms can be present at night, contributing to A.R.'s symptoms of fatigue.

Microbiology

CASE 67-1, QUESTION 2: What are the most likely causes of A.R.'s case of AB?

The causative agent for AB is identified in a minority of cases; however, when pathogens are isolated, they are usually of viral etiology.[2,5–7] A limited number of bacterial pathogens are associated with AB and should primarily be considered in patients with underlying COPD, mechanical ventilation (tracheobronchitis), or in cases of outbreaks and exposures (e.g., Bordetella pertussis). A list of common pathogens with their specific symptoms is included in Table 67-1.[2]

Sick contacts, duration of incubation (2–7 days for viruses vs. weeks for atypical bacteria), and previous exposures should be considered when determining the etiologic agent responsible for AB. Specific symptoms reveal infection caused by specific pathogens, such as an inspiratory whoop and post-tussive emesis (B. pertussis), pharyngitis and cough lasting longer than 4 weeks (Mycoplasma pneumoniae), hoarseness with low-grade fever (Chlamydophila pneumoniae), or cough with fever and myalgias (influenza).[2] Given A.R.'s lack of sick contacts with bacterial infections (his son's recent colds are most likely of viral etiology), time course of present illness, and absence of symptoms suggestive of influenza, a viral etiology (other than influenza) is most likely to be the cause of his symptoms.

Clinical Diagnosis and Treatment

CASE 67-1, QUESTION 3: Should A.R. be provided an antimicrobial agent for his AB?

Antibiotics have not been shown to substantially reduce the duration of illness in AB.[8] Thus, guidelines recommend against the routine use of antimicrobial therapy for AB.[3,6,7,9] Despite these recommendations, antimicrobials are frequently prescribed for this condition.[10] Inappropriate use of antimicrobial therapy is a public health concern because it may lead to adverse events and antimicrobial resistance. One exception to avoidance of antimicrobial therapy in AB is if B. pertussis infection (whooping cough) is suspected. In these cases, antibiotic therapy with a macrolide antibiotic is recommended, and patients should remain in isolation for the first 5 days of treatment to prevent disease transmission.[3] In A.R.'s case, no antimicrobial agent is warranted.

CASE 67-1, QUESTION 4: Should a sputum culture be obtained from A.R.? What other diagnostics should be considered?

Obtaining a sputum sample for culture to determine the presence of the causative agent or diagnostic screening for atypical pathogens is not routinely indicated for AB. The rationale is that most of the identified pathogens have no specific treatment (viral illnesses), and the isolated organisms often are not true pathogens. Diagnostic screening, however, should be performed during influenza season or during outbreaks of B. pertussis or other atypical pathogens for infection control purposes. The use of biomarkers for the diagnosis of bacterial infection, such as procalcitonin or C-reactive protein (CRP), may decrease inappropriate antimicrobial use in AB, but their widespread use cannot be recommended at this time.[13,14]

CASE 67-1, QUESTION 5: What symptom-guided therapies should be offered to A.R.?

Table 67-1

Causes of Acute Bronchitis

Pathogen	Comments
Viruses	
Influenza	Quick onset with fever, chills, headache, and cough. Myalgias are common and may be accompanied by myopathy.
Parainfluenza	Epidemics in autumn. Outbreaks may occur in nursing homes. Croup in child at home suggests presence of the organism.
Respiratory syncytial virus	About 45% of family members exposed to infant with bronchiolitis become infected. Outbreaks prominent in winter or spring. Twenty percent of adults have ear pain.
Coronavirus	Can cause severe respiratory symptoms in elderly. Epidemics present in military recruits.
Adenovirus	Similar presentation as influenza; abrupt onset of fever.
Rhinovirus	Fever is uncommon and infection generally mild.
Atypical Bacteria	
Bordetella pertussis	Incubation period of 1–3 weeks. Whooping occurs in a minority of patients, and fever is uncommon. Marked leukocytosis with lymphocytic predominance can occur.
Mycoplasma pneumoniae	Incubation period is 2–3 weeks. Outbreaks in military personnel and students have been reported.
Chlamydophila pneumoniae	Incubation period is 3 weeks. Onset of symptoms, which include hoarseness before cough, is gradual. Outbreaks reported in nursing homes, college students, and military personnel.

Source: Wenzel RP, Fowler AA 3rd. Clinical practice. Acute bronchitis. N Engl J Med. 2006;355:2125.

Symptom-guided therapies include the use of inhaled β-agonists (albuterol) for shortness of breath, particularly in patients with underlying reactive airway disease; inhaled or systemic steroids for persistent cough; nonsteroidal anti-inflammatory drugs (NSAIDs), aspirin, or acetaminophen to alleviate myalgias or fever; or antihistamines (brompheniramine), antitussives (codeine, dextromethorphan, or benzonatate), or mucolytics (guaifenesin) for cough. These symptom-guided treatments, however, are not backed by strong evidence demonstrating a clear benefit in patients with AB.[1–3,11,12] As such, each of these treatments should be approached with an appropriate consideration of the balance between perceived benefit and risk of adverse events. Given A.R.'s troublesome cough that has kept him up at night, a trial of an antitussive such as dextromethorphan is a reasonable first option. NSAIDs should be avoided given his concurrent aspirin use and lack of clear indication. An inhaled β-agonist or steroid is also not necessary at this time.[12,15]

CASE 67-1, QUESTION 6: Should a chest radiograph be ordered for A.R.? What other illnesses may be considered as the cause of his symptoms?

It is important to distinguish AB from pneumonia with chest radiograph or other imaging tests when fever, tachycardia, tachypnea; physical examination findings such as egophony or rales; or hypoxemia or mental status changes (especially in the elderly) are present.[2],[3] Clinical differentiation of AB from AECOPD, postnasal drip, gastroesophageal reflux disorder (GERD), and asthma must also be made (discussed separately in this chapter and in Chapter 23 Upper Gastrointestinal Disorders, and in Chapter 18 Asthma, respectively). In A.R.'s case, no signs of pneumonia are seen on physical examination or on reviewing symptomatology; therefore, no chest radiograph is warranted. Frequent symptoms over time or risk factors for COPD would warrant an investigation for chronic bronchitis. Wheezing or frequent AB outbreaks and GERD symptoms would guide evaluations for asthma or gastrointestinal disorders, respectively.

Patient Education

CASE 67-1, QUESTION 7: What education would you provide to A.R. to dissuade his perceived need for an antibiotic?

An evaluation of A.R.'s expectations for therapy is important to alleviate concerns about the decision to not to prescribe antimicrobials. Overuse of antibiotics in AB is often driven by either prescriber knowledge or patient request. Communication is key with each patient to provide insight into the potential causative agents of AB, the natural course of the disease, the role of symptomatic relief, and reasons for avoiding prescriptions for antibiotics.

ACUTE EXACERBATION OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Definition, Incidence, and Epidemiology

According to the Global Initiative for Chronic Obstructive Lung Disease (GOLD), Chronic Obstructive Pulmonary Disease (COPD) is a persistent and progressive reduction in airflow that results from repeated exposure to noxious particles. The chronic inflammation in the lungs results in a narrowing of the small airways, destruction of alveoli, and loss of elastic recoil. Of note, COPD may or may not be accompanied by increased sputum production and chronic cough. This disease is also characterized by acute exacerbations (AECOPD), which is defined as a worsening of symptoms that is more severe than the typical day-to-day variations that patients experience during the stable phase of their disease. Acute exacerbations of COPD typically require a change in medication to relieve symptoms and improve outcomes.[16] Maintenance therapy for COPD (discussed separately in Chapter 19 Chronic Obstructive Pulmonary Disease) is often targeted to reduce the severity and frequency of AECOPD.

COPD is associated with high health care expenditures, decreased quality of life, significant morbidity, and high mortality around the world. AECOPD is responsible for most of this burden. In the United States and Canada, COPD is the third and fourth leading cause of death, respectively. In 2009 in the United States, 1.5 million emergency department visits and 715,000 hospitalizations were attributable to COPD.[17] Direct health care costs associated with COPD in 2010 were estimated to be $29.5 billion in the United States.[17] AECOPD is associated with a decrease in quality-of-life measurements and an increase in the rate of decline in lung function, particularly if not treated early.[16]

The primary precipitating factors for AECOPD are infection of the bronchial tree and air pollution.[16],[18–20] As many as one-third of the cases of AECOPD do not have a cause identified.

Pathophysiology

Bacteria, viruses, and pollutants lead to inflammatory responses.[20] Airway inflammation, associated with increases in interleukin-8, tumor necrosis factor-α, and neutrophils, contributes to pulmonary remodeling, decreased ciliary clearance of mucus, worsening airflow obstruction, and the respiratory symptoms associated with AECOPD.

Viruses have been identified as the etiologic cause of AECOPD in up to one-third of the cases, while bacteria have been identified in up to one-half of cases.[20] The micro-organisms most commonly associated with AECOPD include Haemophilus influenza, Streptococcus pneumoniae, and Moraxella catarrhalis. In patients with GOLD 3 (severe) or GOLD 4 (very severe) COPD, Pseudomonas aeruginosa is more prevalent.[16] Many patients with COPD are also colonized with bacteria during the stable phase of their illness.[21] Evidence suggests that either an increased burden of the same colonizing microorganism(s) or acquisition of a new bacterial species may be associated with exacerbating COPD symptoms.[16],[21] Decreases in adaptive immune responses occur as COPD disease progresses, making patients susceptible to more frequent exacerbations caused by bacterial pathogens. Additionally, pathogens associated with exacerbations tend to increase in virulence and antimicrobial resistance as the underlying disease progresses.[16],[19],[20],[22] A possible mechanism for prolonged infection and colonization in patients with COPD is suggested by interactions between both viruses and bacteria altering immune respone.[20]

Clinical Presentation and Diagnosis

Common features of AECOPD include the following: breathlessness, increased cough, increased sputum volume, and increased sputum purulence. In contrast to AB, purulent sputum in AECOPD is associated with an acute bacterial infection.[22] Other less specific symptoms include insomnia, fatigue, tachycardia, tachypnea, and a decrease in exercise tolerance. Patients often report a decrease in ability to conduct activities of daily living.[16]

Diagnostic considerations in the evaluation of patients with AECOPD include pulse oximetry and arterial blood gases, electrocardiogram, and complete blood count including white blood cell (WBC) differential. Chest radiographs are helpful to rule out

pneumonia, pneumothorax, or pleural effusion. An assessment of comorbidities, such as the presence of heart failure or lung diseases (e.g., asthma or lung cancer), should be performed to aid in both prognosis and diagnosis.[16],[18] Collection of sputum samples for Gram stain and culture are not generally recommended, but it may be helpful if patients are failing initial therapies.

Overview of Treatment

Pharmacotherapy directed at AECOPD includes bronchodilators and supplemental oxygen, antimicrobial therapy to decrease the burden of microorganisms, and corticosteroids targeting the inflammatory response.[16],[18] Methylxanthines (aminophylline or theophylline) are rarely used owing to conflicting and limited evidence of efficacy and concerns about toxicity.[16] Nonpharmacologic AECOPD treatment considerations include decisions regarding the site-of-care and the level of respiratory support. These nondrug considerations are not discussed in detail in this chapter but are available in the GOLD Guidelines.[16]

Disease Severity

CASE 67-2

QUESTION 1: T.H. is an 81-year-old white woman presenting to the emergency department (ED) because she “cannot catch my breath.” At baseline she is on 4 L of oxygen continuously via nasal cannula. However, during the last week she has experienced worsening dyspnea necessitating help with daily activities including bathing and feeding. Her daughter had contacted T.H.’s primary-care physician who directed the patient to the ED when T.H. seemed “out of it” and was difficult to arouse. T.H.’s daughter indicates that T.H. has been “having a cold” with increased sputum that is more yellow than in the past with frequent coughing spells. Past medical history is significant for very severe COPD, atrial fibrillation, depression, obstructive sleep apnea, morbid obesity, and a left humerus fracture. No medication allergies are noted. Medications at home include aspirin 81 mg PO daily, citalopram 20 mg PO daily, diltiazem extended-release capsule 240 mg PO daily, salmeterol–fluticasone dry powdered inhaler 50/250 one puff twice daily, and albuterol inhaler four puffs every 6 hours as needed for shortness of breath. Social history is significant for a greater than 80-pack-year history of cigarette smoking, but she quit 4 to 5 years ago. In the ED she was afebrile, heart rate was 96 beats/minute, respiratory rate was 23 breaths/minute, blood pressure was 135/75 mm Hg, and oxygen saturation was 60% on 4 L of oxygen. T.H. is in some distress, alert and oriented times two, and is using accessory muscles for breathing. Initial physical examination was significant for distant breath sounds and decreased air movement bilaterally, a noted absence of lower extremity edema, and an irregularly irregular heartbeat. Laboratory findings are as follows:

Arterial blood gases: pH, 7.34, PCO_2, 60 mm Hg, PO_2, 72 mm Hg

WBC, $9.8 \times 10^3/\mu L$ (neutrophils 71%)
Hemoglobin, 12 g/dL
Platelets, $319 \times 10^3/\mu L$
Sodium, 135 mmol/L
Potassium, 3.7 mmol/L
Chloride, 91 mmol/L
Bicarbonate, 39 mmol/L
Blood urea nitrogen (BUN), 15 mg/dL
Serum creatinine (SCr), 1.21 mg/dL
Glucose, 104 mg/dL
Brain natriuretic peptide, 66 pg/mL
Troponin, <0.07 ng/mL
Thyrotropin, 1.63 micro-international units/mL

Chest radiograph indicated small pleural effusions, but it was otherwise negative for infiltrates or consolidation. An electrocardiogram indicated the presence of atrial fibrillation. Pulmonary function tests (obtained 1 year ago) indicated an FEV_1 to forced vital capacity ratio of 0.39 and an FEV_1 of 37% predicted. How would you stage the severity of this exacerbation for T.H.?

T.H. has several risk factors for a poor outcome, including the presence of atrial fibrillation and severe COPD defined by her home oxygen requirement and low baseline FEV_1.[16]

Clinical signs and symptoms consistent with a severe exacerbation include the use of accessory respiratory muscles, paradoxical chest wall movements, worsening or new cyanosis, peripheral edema, hemodynamic compromise, signs of right heart failure, and alterations in mental status. T.H. has two of these factors: reduced alertness and use of accessory muscles.[16,18]

Disease Prevention

CASE 67-2, QUESTION 2: Which therapies should be made available to T.H. to alleviate her shortness of breath?

Supplemental oxygen to alleviate hypoxemia is a foundation of treatment for AECOPD. Controlled provision of oxygen should be implemented to provide an oxygen saturation of greater than 90% or a Pao_2 of greater than 60 mm Hg. Hypoxia that is not easily reversible warrants further examination for venous thromboembolism, pneumonia, or other causes. A repeat arterial blood gas should be obtained within 1 hour of initiation of supplemental oxygen to assess for carbon dioxide retention or acidosis.

The use of short-acting bronchodilators should be initiated promptly in all patients with AECOPD. β-Agonists, such as albuterol, with or without an anticholinergic agent (ipratropium), are the preferred agents.[16] If the patient does not respond, a methylxanthine (theophylline or aminophylline) may be considered as second-line therapy. There is no role for long-acting bronchodilators in AECOPD at this time.

CASE 67-2, QUESTION 3: Does T.H. need to be treated with antimicrobial therapy?

The "cardinal" symptoms of AECOPD include increases in sputum purulence, sputum volume, and dyspnea.[23] The use of cardinal symptoms as a method of staging AECOPD severity has been used in several prospective studies and is recommended in the GOLD guidelines.[16],[24]

Experts advocate for the use of antibiotics for AECOPD, particularly when two or three cardinal symptoms are present.[16],[18] Specifically, the GOLD Guidelines recommend antibiotics for patients with three cardinal symptoms (increased dyspnea, increased sputum volume, and increased sputum purulence); when two cardinal symptoms are present if increased sputum purulence is one of the symptoms; or in all patients requiring mechanical ventilation for their AECOPD.[16]

T.H. is exhibiting all three of the cardinal symptoms and therefore should receive antibiotics. Likely benefits would be enhanced treatment success, prevention of relapse, decreased risk for rehospitalization, improvement in pulmonary function, and reduction of the severity of her exacerbation.

CASE 67-2, QUESTION 4: Which antimicrobial agent should be selected for treating T.H.? What duration of treatment would be recommended?

Given T.H.'s history, diminished mental status, and risk factors for poor outcomes, intravenous (IV) administration seems appropriate for the initial antibiotic administration. Potential risk factors for P. aeruginosa should be evaluated. If T.H. demonstrates risk factors for P. aeruginosa, an anti-pseudomonal β-lactam, such as cefepime, would be an appropriate initial agent. If no risk factors for P. aeruginosa exist, a β-lactam/β-lactamase inhibitor such as ampicillin/sulbactam, a third-generation cephalosporin such as ceftriaxone, or a respiratory fluoroquinolone such as moxifloxacin or levofloxacin should be selected. All these therapies are active against drug-resistant S. pneumoniae (DRSP). If T.H. improves on one of these parenteral agents and is ready for discharge, T.H. could transition to an oral respiratory fluoroquinolone or high doses of amoxicillin/clavulanate.

Another important consideration for initial selection of antimicrobials is an evaluation of antibiotic history. Alternative antimicrobials from another class should be considered if patients have been previously treated in the last 3 months.[16] Additionally, if no improvements in symptoms occur within 72 hours, consider obtaining a sputum sample for directed therapy.[16]

The duration of treatment of antibiotics for AECOPD suffers from lack of solid evidence-based recommendation. Given findings from CB investigations, a duration of 5 to 10 days has been suggested, but this is an area in need of further research.[16]

CASE 67-2, QUESTION 5: Should T.H. be treated with corticosteroids? If so, which dose and duration would be selected?

In the setting of AECOPD, systemic corticosteroids help to improve lung function, shorten recovery time, and prevent relapses. Based on available evidence, the GOLD Guidelines recommend a corticosteroid regimen of 40 mg/day of prednisone for 5 days in patients with AECOPD.[16] This regimen would be appropriate for T.H., although an equivalent intravenous regimen could be considered if she was not able to take an oral regimen. Higher doses and longer durations of therapy have not been found to confer a clinical advantage, and intravenous and oral regimens are considered equally effective.[25],[26] In those patients receiving more than 3 weeks of steroids or multiple course of steroids in the previous months, tapering the dose should be considered. Although it is more expensive, nebulized budesonide may be considered as an alternative to oral corticosteroids for treatment of AECOPD.[16]

Enhancing Patient Outcomes

CASE 67-2, QUESTION 6: What factors should be assessed for T.H. during her hospitalization, and what follow-up should be planned to help assure she recovers fully and is not readmitted for COPD?

Hospitalized patients with AECOPD should both be optimally treated, and their COPD management be assessed to decrease the likelihood of readmission. T.H.'s baseline COPD medications should be examined and adjusted based on disease severity (see Chapter 19 Chronic Obstructive Pulmonary Disease for details). Additionally, an assessment of her understanding of the role of medications (maintenance therapy vs. rescue medications), ability to use inhalers correctly, access to her prescribed medications, and discussions regarding pulmonary rehabilitation should take place.[16],[17] Consideration for pharmacologic venous thromboembolism prophylaxis (see Chapter 11 Thrombosis) should also be made in this high-risk population.[16],[27]

PREVENTION OF COMMON RESPIRATORY INFECTIONS BY VACCINATION

CASE 67-2, QUESTION 7: Which vaccines should be considered for T.H. as part of her COPD management?

Vaccination records for influenza and S. pneumoniae should be evaluated in T.H. Annual influenza vaccination is recommended for all patients ≥6 months with COPD, and it has been shown to reduce the risk of AECOPD.[16],[17] Vaccination against S. pneumoniae with the 23-valent polysaccharide vaccine is recommended for patients ≥19 years old with COPD. Unlike the influenza vaccine, however, vaccination against S. pneumoniae has not been clearly linked with a reduced risk of AECOPD. The pneumococcal vaccine is recommended by guidelines, however, as part of the overall health plan of the patient.

COMMUNITY-ACQUIRED PNEUMONIA

Definition, Incidence, and Epidemiology

Pneumonia is an infection of the lung parenchyma. Community- acquired pneumonia (CAP) refers to pneumonia acquired in the absence of health care system exposure (i.e., hospital, long-term care, chronic antibiotic exposure). Diagnosis is dependent upon clinical features and radiologic evidence of an infiltrate, but it may be further supported by physical examination and/or hypoxemia.

Current estimates show that CAP accounts for 24.8 cases per 10,000 discharges in the US adult population with the elderly being primarily affected (65–79 years: 63/10,000; ≥80 years: 164.3/10,000).[28] In the pediatric population, CAP accounts for 15.7 cases per 10,000 discharges, with infants and young children showing increased risk (<2 years: 62.2/10,000).[29] The overall mortality rate for patients ≥65 years is 5.6% and is more pronounced in hospitalized patients (8.5%) compared to outpatients (3.8%).[30] Seventeen percent of older patients who develop CAP will suffer cardiac complications.[31]

Pathophysiology

Development of CAP occurs through the inhalation of infectious particles via droplets or aerosols, or the aspiration of oral flora. Rarely, hematogenous spread of bacteria from distant sources into the lungs may occur, as well as direct extension of infection to the lung from contiguous areas, such as the pleural or subdiaphragmatic spaces.

Once bacteria reach the tracheobronchial tree, defects in local pulmonary defenses facilitate infection. Contributing factors include inflammation-mediated injury to bronchial epithelium leading to depressed mucociliary clearance and a blunted cellular and humoral response. Patients with underlying or acquired immunodeficiencies are at an increased risk.

Clinical Presentation and Diagnosis

In the majority of CAP cases, patients present acutely with high fever, chills, tachypnea, tachycardia, and productive cough. Physical examination findings are usually localized to a specific lung zone and can include crackles, rhonchi, bronchial breath sounds, dullness, or egophony. On rare occasions, CAP exhibits a subacute presentation with fever, nonproductive cough, constitutional symptoms, and absent or diffuse findings on lung examination. Children with CAP may present with vomiting.

A chest radiograph or other imaging technique revealing an infiltrate is required for the diagnosis of CAP.[32] Radiographic manifestations of diseases such as congestive heart failure and malignancy can obscure the infiltrate, reinforcing the need to utilize both clinical and chest radiographic findings.

Pretreatment blood cultures and a respiratory sample (expectorated or induced sputum or endotracheal aspirate in intubated patients) should be obtained for culture and Gram stain. Although these cultures are often negative, when they are positive, they allow fine-tuning of the empirical antibiotic selection.

Overview of Drug Therapy

Antibiotic therapy for CAP is empirical in the majority of cases and should always be based on the most likely pathogen(s), underlying patient characteristics, and the severity of disease. Based on these variables, clinicians can triage patients for risk of infection caused by antibiotic-resistant pathogens and appropriately tailor therapy.

CLINICAL PRESENTATION

CASE 67-3

QUESTION 1: J.T. is a 45-year-old woman presenting to the ED with fevers, chills, and chest pain. Her symptoms have persisted for 4 days, and she has a productive cough with rusty-colored sputum and dyspnea on exertion. She has had no recent illnesses and no known sick contacts, but she was recently released from a 2-year period of incarceration. She has tried acetaminophen to alleviate her fever and chest pain. Past medical history is positive for asthma, for which she is prescribed fluticasone and albuterol, and depression, for which she takes paroxetine. Vital signs reveal a temperature of 40.1°C, heart rate of 128 beats/minute, blood pressure of 130/76 mm Hg, and respiratory rate of 32 breaths/minute with accompanying oxygen saturation of 85% on 5 L of oxygen by nasal cannula. The remainder of the physical examination is notable for orientation to person but not place or time and for diffuse crackles bilaterally, which are most apparent on the right side. Laboratory results include the following:

WBC count, 15,500 cells/μL
Hematocrit, 29.3%
Sodium, 133 mmol/L
Potassium, 3.8 mmol/L
BUN, 23 mg/dL
SCr, 0.8 mg/dL
HCO_3, 28 mEq/L
Glucose 148, mg/dL
Arterial blood gases: pH 7.42, PO_2, 61 mm Hg, PCO_2, 46 mm Hg

A test for human immunodeficiency virus is negative. Chest radiograph reveals a right lower lobe infiltrate. What signs, symptoms, and tests are consistent with CAP in J.T.?

In the majority of cases, patients with CAP present with cough with sputum production, dyspnea, and pleuritic chest pain.[33] Patients may show signs of the systemic inflammatory response syndrome, including tachycardia, tachypnea, fever, and an abnormal WBC count.[34] Auscultatory examination often reveals decreased breath sounds, crackles or rhonchi, or egophony in patients with consolidation. Signs and symptoms associated with severe pneumonia are grouped into minor and major criteria defined by the Infectious Disease Society of America (IDSA)/American Thoracic Society (ATS) Guidelines for CAP.[32] Minor criteria include respiratory rate greater than 30 breaths/minute at admission; ratios of the Pao_2 to fraction of inspired oxygen (FIO_2) (Pao_2/FIO_2) less than 250 mm Hg; systolic blood pressure (SBP) less than 90 mm Hg, or diastolic blood pressure (DBP) less than 60 mm Hg; confusion; multilobar infiltrates; SBP less than 90 mm Hg despite aggressive fluid resuscitation; BUN of at least 20 mg/dL; leukopenia; thrombocytopenia; and hypothermia. Major criteria include requirement of mechanical ventilation and requirement of vasopressors for more than 4 hours.[32]

Clinical findings and a positive infiltrate by chest radiograph or other imaging technique is required for the diagnosis of pneumonia.[32] Patients who are hospitalized based on clinical symptoms absent of positive imaging should have repeat imaging performed 24 to 48 hours post-admission.

Disease Severity

CASE 67-3, QUESTION 2: Given the clinical condition of J.T. in the ED, where should her care be continued?

The first decision after a diagnosis of CAP is to determine whether the patient requires hospitalization. Several predictive rules have been developed to facilitate site-of-care decision making. The two best-studied tools that are endorsed by the IDSA/ATS guidelines are the pneumonia severity index (PSI) and the CURB-65 rule.

The PSI uses individually scored demographic characteristics (age, gender, nursing home residence), comorbidities (liver disease, CHF, renal disease, neoplasm), physical examination findings (mental status, RR, SBP, temp, HR), and laboratory data (Na^+, glucose, Hct, BUN); the total PSI score categorizes patients into one of five classes that are associated with an escalating risk of death (Table 67-2).[35] The CURB-65, developed by the British Thoracic Society, is a simple tool that focuses on five assessments: confusion (owing to pneumonia), uremia (BUN >19 mg/dL), respiratory rate of at least 30 breaths/minute, SBP less than 90 mm Hg systolic or DBP less than 60 mm Hg, and age of at least 65 years.[36] Each criteria receives one point, and the cumulative score is associated with a specific (rising with higher score) 30-day mortality risk. Based on the score, subsequent care should be as follows: 0–1 = outpatient; 2 = admission to ward; ≥3 = ICU care. Both scales identify patients at low risk of death, but the CURB-65 has been found to be more discerning of patients who need ICU care and with the highest risk of death.[37] The need for ICU admission can be subjective; however, the IDSA/ATS guidelines recommend that patients with three or more minor criteria, or at least one major criteria for severe CAP, be admitted to the ICU.[32]

CASE 67-3, QUESTION 3: What testing should be performed to obtain a microbiologic diagnosis in J.T.?

Patient J.T. can be assessed as follows using the PSI: 45-year-old woman (35 points [45 for age – 10 for gender female]), respiratory rate greater than 30 breaths/minute (20 points), heart rate greater than 125 beats/minute (20 points), temperature greater than 40°C (15 points), hematocrit less than 30% (10 points), and altered mental status (20 points). A total score of 120 points places J.T. in risk strata IV (30-day mortality risk: 9.3%–27%), and she should be admitted to the hospital, potentially to the ICU. Using the CURB-65, J.T. has a score of 3 (30-day mortality of 9.2%) based on uremia, confusion, and increased respiratory rate, and she should be admitted to the ICU.

Microbiologic testing is optional for outpatients with CAP. However, the IDSA/ATS guidelines recommend attempting to make a microbiologic diagnosis in patients with CAP who are hospitalized.[32] Microbiologic diagnosis (via sputum or endotracheal aspirate) can help guide empiric therapy as well as identify rare and usual etiologies and cluster cases.

Table 67-2

Predicted Pneumonia Mortality and Recommended Site of Care

System and Score	Predicted 30-Day Mortality (%)	Recommended Site of Care
PSI strata I–II (≤70)	0.1–0.7	Outpatient
PSI strata III (71–90)	0.9–2.8	Admit to hospital ward
PSI strata IV–V (≥91)	9.3–27	Admit to hospital; consider ICU
CURB-65 score 0–1	0.7–2.1	Outpatient
CURB-65 score 2	9.2	Admit to hospital ward
CURB-65 score ≥3	14.5–57	Admit to ICU

CURB-65, confusion, uremia, increased respiratory rate, low blood pressure, and age ≥65 years; ICU, intensive care unit; PSI, pneumonia severity index.

Source: Fine MJ et al. A prediction rule to identify low-risk patients with community-acquired pneumonia. N Engl J Med. 1997;336:243.

Urine antigen tests for pneumococcus and Legionella pneumophila serogroup 1 are available for patients with severe CAP. Both tests are sensitive (>80%) and specific (>90%), and have the advantage of detecting pathogens after antibiotics have been administered.

The IDSA/ATS guidelines recommend consideration of influenza testing during traditional "flu season" and during times of an outbreak.[32] Detection of influenza should be via reverse transcriptase polymerase chain reaction (RT-PCR), which is the most sensitive and specific method, with a quick turnaround time for results (4–6 hours).[38] Rapid influenza antigen detection tests may be used, but because of lower sensitivity and specificity RT-PCR is recommended to confirm negative test results reported by the rapid antigen test. Viral isolation in standard cell culture should be routinely performed with respiratory specimens during the influenza season.

Microbiology

CASE 67-3, QUESTION 4: What pathogens are most likely in J.T.?

The major pathogens for CAP are summarized in Table 67-3. The most frequently isolated bacterial pathogen, regardless of epidemiologic factors and severity of illness, accounting for approximately 27% of CAP worldwide, is S. pneumoniae.[32] Two survival strategies are utilized by S. pneumoniae.[39] The first is related to a noninvasive phenotype that uses surface adhesions, immune evasion strategies, and secretory defenses to promote long-term carriage within the nasopharynx. Deficits in host defense, such as an immunocompromised state, allow colonizing strains of low virulence to cause invasive disease. The second survival strategy depends on efficient person-to-person transmission and associated rapid disease induction by an invasive phenotype. Age younger than 2 or older than 64 years, asplenia, alcoholism, diabetes mellitus, antecedent influenza, defects in humoral immunity, and human immunodeficiency virus infection are risk factors for the invasive pneumococcal phenotype.[40] Other risk factors less likely to be associated with invasive disease include poverty and crowding, cigarette smoking, chronic lung disease, severe liver disease, recent exposure to antibiotics, and chronic proton-pump inhibitor use.

Following the introduction of the first pneumococcal conjugate vaccine in 2000 (PCV7) and the expanded PCV13 in 2010, the incidence of invasive disease and all-cause pneumonia have significantly fallen. The advent of these vaccines has not led to a significant pneumonia decline in high-risk pediatric patients, specifically children younger than 5 years with moderate-to-severe asthma, or asthma with one or more of the following comorbid conditions: heart disease, lung disease, diabetes, or neuromuscular disease.[40] The effect of the newly approved pneumococcal polysaccharide vaccine (PPSV23) on the high-risk populations has yet to be realized.

Atypical pathogens, including L. pneumophila, C. pneumoniae, and M. pneumoniae, account for approximately 25% of CAP worldwide.[41] However, atypical pathogens may be present in up to 60% of CAP episodes because of coinfection.[42] Polymicrobial infection including atypical pathogens may lead to a more complicated course with extended lengths of stay. Several studies have shown that antibiotic regimens that include coverage against these pathogens demonstrate a survival benefit over regimens that do not.[43–47] Legionnaires' disease, caused primarily by L. pneumophila serogroup 1, accounts for 2% to 7% of CAP.[42] CAP caused by L. pneumophila is considered to be more severe among hospitalized patients, and it may present with high fever, nonproductive cough, low serum sodium concentration, high concentration of lactate dehydrogenase, and low platelet counts.[48],[49]

Table 67-3

Microorganisms Common in Community-Acquired Pneumonia

Ambulatory	Hospitalized, Non-ICU	Hospitalized, ICU
Streptococcus pneumoniae	S. pneumoniae	S. pneumoniae
Mycoplasma pneumoniae	M. pneumoniae	S. aureus
Haemophilus influenzae	C. pneumoniae	Legionella species
Chlamydophila pneumoniae	Staphylococcus aureus	Gram-negative bacilli
Respiratory viruses[a]	H. influenzae	H. influenzae
	Legionella species	
	Respiratory viruses[a]	

[a] Influenza A and B, adenovirus, respiratory syncytial virus, and parainfluenza.

Table 67-4

Community-Acquired Pneumonia: Underlying Conditions and Commonly Encountered Pathogens

Condition	Commonly Encountered Pathogen(s)
Alcoholism	Oral anaerobes, Klebsiella pneumoniae, Acinetobacter sp., Mycobacterium tuberculosis
COPD or smoking	Pseudomonas aeruginosa, Legionella sp.
Aspiration	Gram-negative enteric pathogens, oral anaerobes
Lung abscess	CA-MRSA, oral anaerobes, endemic fungal pneumonia, M. tuberculosis, atypical mycobacteria
Exposure to bat or bird droppings	Histoplasma capsulatum
Exposure to birds	Chlamydophila psittaci (if poultry: avian influenza)
Exposure to rabbits	Francisella tularensis
Exposure to farm animals or parturient cats	Coxiella burnetii (Q fever)
HIV infection (early)	M. tuberculosis
HIV infection (late)	M. tuberculosis, Pneumocystis jiroveci, Cryptococcus sp., Histoplasma sp., Aspergillus sp., atypical mycobacteria (especially Mycobacterium kansasii), Pseudomonas aeruginosa
Hotel or cruise ship stay in previous 2 weeks	Legionella sp.
Travel to or residence in southwestern United States	Coccidioides sp., hantavirus
Travel to or residence in Southeast and East Asia	Burkholderia pseudomallei, avian influenza, SARS
Cough >2 weeks with whoop or post-tussive vomiting	Bordetella pertussis
Structural lung disease (e.g., bronchiectasis)	P. aeruginosa, Burkholderia cepacia, Staphylococcus aureus
Injection drug use	S. aureus, anaerobes, M. tuberculosis
Endobronchial obstruction	Anaerobes, S. aureus
In context of bioterrorism	Bacillus anthracis (anthrax), Yersinia pestis (plague), F. tularensis (tularemia)

CA-MRSA, community-acquired methicillin-resistant Staphylococcus aureus; COPD, chronic obstructive pulmonary disease; HIV, human immunodeficiency virus; SARS, severe acute respiratory syndrome.

Source: Mandell LA et al. Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults. Clin Infect Dis. 2007;44(Suppl 2):S27.

Epidemiologic factors may favor the presence of certain bacterial pathogens and are listed in Table 67-4.[32] This highlights the importance of the performance of a thorough patient history to assist in the direction of therapy. Additional factors such as chronic oral steroid use (≥10 mg prednisone/day), immunosuppression, and frequent antibiotic therapy will likely place the patient into the category of health care–associated pneumonia (HCAP), which will require augmented therapy options.[49]

S. aureus is recognized as a major cause of nosocomial pneumonia; however, its significance in CAP is less clear. Traditionally, S. aureus has not been considered a common cause of CAP (approximately 2.5% of cases), but it is most likely to occur in association with influenza or in patients with lung abscess.[32],[50] Community-associated MRSA (CA-MRSA) is significantly different from the typical hospital-acquired strain. These differences include susceptibility to non–β-lactam antibiotics (e.g., clindamycin and doxycycline) and clinical syndrome (necrotizing radiographic presentation, empyema formation, hemoptysis, and profound hypoxemia) associated with toxins including Panton–Valentine leukocidin.[51] Toxin-producing strains are also part of methicillin-sensitive S. aureus's (MSSA) virulence.[52] The outcomes of patients with MRSA and MSSA CAP are similarly poor with prolonged length of hospital stay and a nearly 25% mortality.[53]

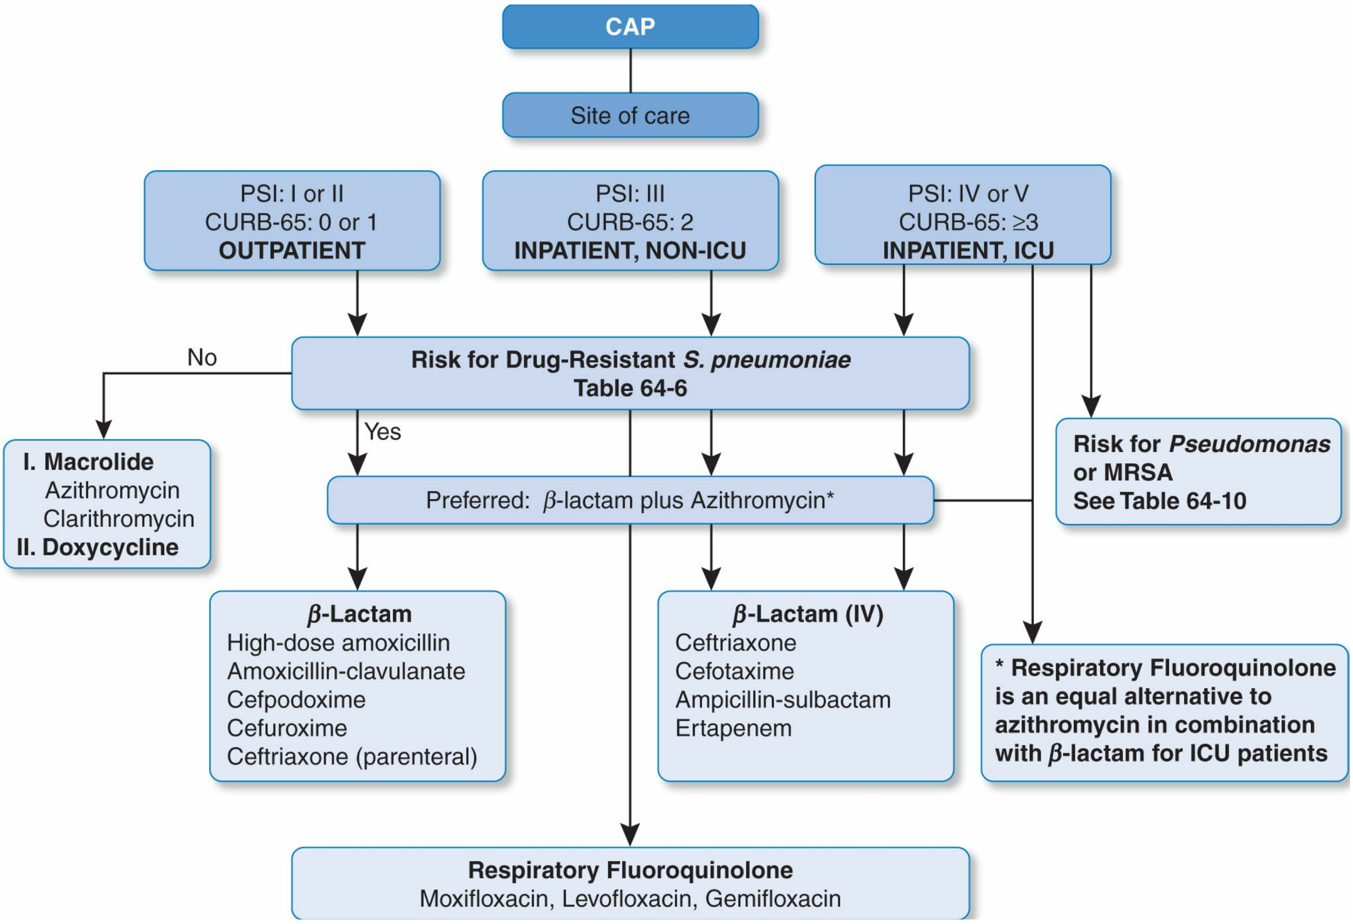
The influenza A H1N1 outbreak in 2009 highlighted the contribution of respiratory viruses as an etiology of CAP. Respiratory virus can be the primary cause of CAP, but it can also be a major contributing factor that predisposes the patient to infection by another pathogen, often bacterial (11%–15%). Using contemporary nucleic acid amplification tests, the incidence of viral CAP ranges from 19% to 32%.[54–56] Respiratory viruses that cause CAP include influenza A and B, respiratory syncytial virus, rhinovirus, parainfluenza, adenovirus, human metapneumovirus, and coronavirus. In patients coinfected with both viral and bacterial pathogens, the most common bacteria are S. pneumoniae, S. aureus, and atypicals.

Possible microbes causing J.T.'s CAP include S. pneumoniae, M. pneumoniae, C. pneumonia, S. aureus, H. influenzae, Legionella species, and respiratory viruses.

Antibiotic Therapy

CASE 67-3, QUESTION 5: Which antimicrobial agent(s) should be chosen for the initial management of J.T.?

An approach to the patient with CAP, and recommended antibiotic regimens based on the patient's site of care and severity of illness, are provided in Figure 67-1. Delayed antibiotic therapy has been associated with an increased length of hospital stay and decreased survival in CAP; therefore, a rapid and correct diagnosis is imperative.[57],[58] The most recent IDSA/ATS CAP treatment guidelines recommend the first dose of antibiotic be given in the ED in an effort to avoid treatment delays associated with the hospital admission process.[32]



CAP
Site of care
PSI: I or II

Figure 67-1 Approach to empiric antibiotic therapy in patients with community-acquired pneumonia. CAP, community-acquired pneumonia; CURB-65, confusion, uremia, respiratory rate, blood pressure, and age of at least 65 years; IV, intravenous; MRSA, methicillin-resistant Staphylococcus aureus; PSI, pneumonia severity index.

All patients should be empirically treated for pneumococcus and atypical pathogens. The choice of the initial regimen should be based on medical comorbidities or epidemiologic factors, including the possibility of antibiotic-resistant causative organisms. Factors that increase the risk of DRSP are located in Table 67-5.

Macrolide antibiotics (e.g., azithromycin and clarithromycin) or doxycycline are preferred as monotherapy for noncomplicated outpatient treatment and are used in combination with β-lactams for complicated outpatients and those treated on inpatient wards.[32] Macrolides should not be employed as monotherapy for inpatient care, as nearly 30% of pneumococcal isolates demonstrate resistance.[59] Several mechanisms are responsible for macrolide resistance, including ribosomal modification mediated by erm (B), efflux from the bacterial cell controlled by mef (A), or a combination of both.

Table 67-5

Risk Factors for α-Lactam-Resistant Streptococcus pneumoniae

Age <2 or >65 years
β-Lactam therapy within the previous 3 months (also at risk for organisms associated with HCAP)

Alcoholism
Medical comorbidities
Immunosuppressive illness or therapy (also at risk for organisms associated with HCAP)
Exposure to a child in a day-care center

HCAP, health care–associated pneumonia.

Source: Mandell LA et al. Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults. Clin Infect Dis. 2007;44(Suppl 2):S27.

Patients with comorbidities, exposure to antibiotics within the past 3 months, DRSP risk factors, or who live in an area with a high prevalence of DRSP should receive a combination β-lactam and macrolide regimen or a respiratory fluoroquinolone (e.g., levofloxacin, moxifloxacin, and gemifloxacin).[32] Preferred β-lactams include high-dose amoxicillin (1 g PO TID), amoxicillin-clavulanate (2 g PO BID), or ceftriaxone (1–2 g IV daily). β-lactam resistance occurs through alteration of one or more of the penicillin-binding proteins that mediate the bacterial cell wall production.[60] Penicillin-binding protein alterations in resistant strains decrease the affinity to all β-lactams such that higher concentrations are required for binding and inhibition of the enzyme. Thus, appropriate dosing of β-lactams in the treatment of CAP minimizes development of resistance and promotes optimal clinical outcomes.[61],[62] Fluoroquinolones are the preferred agents for CAP in penicillin-allergic patients. Fluoroquinolone resistance, mediated by mutations in the DNA gyrase gene gyrA and the topoisomerase IV genes parC and parE, as well as efflux pump–mediated, has increased because of their widespread use; however, overall pneumococcal resistance rates are low.[63] IDSA/ATS guideline-concordant therapy for hospitalized patients has been associated with improved patient outcomes including decreases in time to achieve clinical stability, total duration of parenteral therapy, and hospital length of stay, as well as improved in-hospital survival.[64],[65]

J.T.'s treatment should be started in the ED after obtaining a respiratory specimen and pretreatment blood cultures for Gram stain and culture. J.T. does not possess risk factors for specific bacteria, such as Enterobacteriaceae or P. aeruginosa; therefore, a β-lactam (ceftriaxone) plus a macrolide (azithromycin) should be initiated empirically, both initially given parenterally. Consideration of CA-MRSA infection should be made given J.T.'s recent incarceration and profound hypoxemia, although the rest of her clinical presentation is not compatible with this etiology.

CASE 67-3, QUESTION 6: What is the appropriate length of therapy for J.T.?

A definitive duration of treatment for CAP has not been well established. Significant variation in duration of treatment exists and is independent of severity of CAP.[66] The IDSA/ATS guidelines recommend treatment for a minimum of 5 days, and patients should be afebrile for 48 to 72 hours before therapy is discontinued. In addition, patients should not have therapy discontinued if they have two or more CAP-associated signs of clinical instability, including temperature of greater than 37.8°C, heart rate of greater than 100 beats/minute, respiratory rate of greater than 24 breaths/minute, SBP of less than 90 mm Hg, arterial oxygen saturation of less than 90% or Pao_2 of less than 60 mm Hg on room air, inability to maintain oral intake, or abnormal mental status. Evidence suggests that longer courses of therapy (>7 days) are no more effective than shorter courses (3–7 days).[67]

Serial monitoring of infection biomarkers may guide duration of antibiotic therapy. A fall in procalcitonin (PCT), a calcitonin precursor elevated in infection, trauma, and burns, has been associated with a significant reduction in total duration of antibiotic use compared with standard care and may be a useful indicator of adequate therapy.[68]

CASE 67-4

QUESTION 1: F.E. is a 56-year-old man presenting to the ED with the complaints of fever, chills, nausea, and vomiting for the last 7 days, and more recently, shortness of breath with productive cough with white sputum for the past 4 days. He visited his family approximately 2 days prior to symptoms, where two of his relatives were thought to have an unconfirmed viral illness. Initial assessment reveals the patient to be alert and oriented times three, but falling asleep during assessment, pulses present with brisk capillary refill, decreased lung sounds bilaterally, and no peripheral edema. Past medical history is significant for hypertension and diabetes mellitus. The patient has an allergy to penicillin, with a reported reaction of rash. Medications at home include aspirin 81 mg PO daily, hydrochlorothiazide 25 mg PO daily, lisinopril 20 mg PO daily, and atorvastatin 40 mg PO daily. Social history is significant for smoking one pack of cigarettes per week. In the ED he had a temperature of 38.9°C, heart rate of 112 beats/minute, respiratory rate of 22 breaths/minute, SBP/DBP of 126/80 mm Hg, and oxygen saturation of 93% on 2 L. Laboratory results include the following:

WBC count,	2,900 cells/μL
Hematocrit,	47.1%
Platelets	129,000 cells/μL
Sodium,	127 mmol/L
Potassium,	4.6 mmol/L
BUN,	7 mg/dL
SCr,	0.73 mg/dL
Glucose	117, mg/dL

Chest radiograph showed bilateral interstitial infiltrates; RT-PCR was positive for influenza A. What is the most likely reason for F.E.'s influenza infection?

Influenza viruses spread when an infected person coughs or sneezes near a susceptible person.[69] The usual incubation period for influenza is 1 to 4 days, and the time between onset among patients who have come into contact with one another is likely to be 3 to 4 days.[70] Adults can shed influenza virus from the day before symptoms begin through 5 to 10 days after illness onset.[71] Young children shed virus several days before illness onset, and they can be infectious for 10 days or more after onset of symptoms. Prolonged viral replication can occur in adults with severe disease, including those with comorbidities or those receiving corticosteroid therapy.[72],[73] Severely immunocompromised persons can shed virus for weeks to months.[74],[75]

CASE 67-4, QUESTION 2: Should F.E. be treated with antiviral agents?

Patients with laboratory-confirmed influenza virus or high-risk patients suspected of infection (Table 67-6) should receive antiviral therapy within 48 hours of symptom onset whether or not they are hospitalized. Non-improving high-risk patients or those with symptoms greater than 48 hours and requiring hospitalization should also be treated. F.E. falls into the latter category and should be treated for influenza A.[38] Antibiotic treatment is recommended for hospitalized patients with CAP, even if influenza is suspected, and therapy should be directed at likely bacterial pathogens associated with influenza such as S. pneumoniae, S. pyogenes, and S. aureus, including MRSA.[32]

Antiviral Therapy

CASE 67-4, QUESTION 3: Which antiviral agent(s) should F.E. be treated with?

Table 67-6

Patients at High Risk of Complications from Influenza

Unvaccinated infants aged 12–24 months
Persons with asthma or other chronic pulmonary diseases (e.g., COPD, cystic fibrosis)
Persons with hemodynamically significant cardiac disease
Persons with immunosuppressive disorders or who are receiving immunosuppressive therapy
HIV-infected persons
Persons with sickle cell anemia and other hemoglobinopathies
Persons with diseases that require long-term, high-dose aspirin therapy, such as rheumatoid arthritis
Persons with chronic renal dysfunction
Persons with cancer
Persons with chronic metabolic disease, such as diabetes mellitus
Persons with central nervous system disorders that may compromise the handling of secretions such as neuromuscular disorders, cerebral vascular accidents, or seizure disorders
Adults aged ≥65 years
Residents of any age of nursing homes or other long-term care institutions

COPD, chronic obstructive pulmonary disease; HIV, human immunodeficiency virus.

Influenza susceptibility profiles to antiviral agents evolve rapidly, and treating clinicians should be familiar with updated resistance data found at the Centers for Disease Control and Prevention website: www.cdc.gov/flu. Neuraminidase inhibitors including oseltamivir or zanamivir are the primary antiviral agents recommended for the treatment of influenza (Table 67-7).[38] The inhibition of neuraminidase prevents cleavage of sialic acid residues on the cell surface of the virus, thereby preventing the release of virus from infected cells. Considering the high rate of resistance, adamantines (amantadine and rimantadine) are not currently recommended for treatment of influenza. FE should be treated with either oseltamivir 75 mg PO BID or zanamivir 10 mg inhaled every 12 hours. Both medications should be used for a total of 5 days.

Neuraminidase inhibitors should be initiated as soon as possible after illness onset, ideally within 48 hours, as this is when the majority of viral replication occurs. However, treatment of any person with confirmed or suspected influenza requiring hospitalization is recommended for up to 96 hours post-illness onset.[76],[77] For patients whose illness is prolonged, treatment regimens may need to be extended beyond 5 days.

Development of resistance to zanamivir or oseltamivir has been identified during treatment of seasonal influenza.[78] Oseltamivir resistance is caused by a specific mutation leading to a histidine to tyrosine substitution (H275Y) in neuraminidase.[79] Oseltamivir resistance, which can occur within one week of treatment initiation, has been reported particularly among immunocompromised patients infected with the 2009 H1N1 virus.[80],[81]

HOSPITAL-ACQUIRED PNEUMONIA, AND VENTILATOR-ASSOCIATED PNEUMONIA

Definitions and Incidence

Despite advances in therapy and prevention, hospital-acquired pneumonia (HAP) and ventilator-associated pneumonia (VAP) are associated with significant morbidity and mortality. HAP is defined as pneumonia that occurs at least 48 hours after hospital admission. VAP refers to pneumonia that arises 48 to 72 hours after endotracheal intubation. HCAP occurs within 48 hours of admission in patients with previous risk factors for infection caused by potentially drug-resistant pathogens, including hospitalization in an acute-care hospital for 2 or more days within 90 days of infection; residence in a nursing home or long-term care facility; receipt of recent IV antibiotic therapy, chemotherapy, or wound care within the past 30 days of the current infection; living in close contact with a person with a multidrug-resistant pathogen; or attending a hospital or hemodialysis clinic.[49]

Epidemiology

HAP is the second most common nosocomial infection in the United States, with urinary tract infections as the most common.[49] Based on a prospective cohort study, approximately 7% of ICU patients developed HAP and over 75% of them had VAP. [82] A retrospective cohort study of 4,543 hospitalized patients with culture-positive pneumonia observed that HCAP accounted for 21.7% of the cases, HAP for 18.4%, and VAP for 11%. Mortality rates associated with HAP groups were comparable (19.8% and 18.8%, respectively) and both were significantly lower than those for VAP (29.3%). Mean lengths of stay differed with pneumonia category: HAP patients for 15.2 ± 13.6 days, and VAP patients for 23 ± 20.2 days.[83]

The disease onset is an important epidemiologic variable and risk factor for specific pathogens and outcomes in patients with HAP and VAP. Early-onset HAP and VAP are defined as occurring within the first 4 days of hospitalization, usually carry a better prognosis, and are more likely caused by antibiotic-sensitive bacteria. Late-onset HAP and VAP (occurring after ≥5 days of hospitalization) are more likely to be caused by multidrug-resistant (MDR) pathogens and are associated with increased morbidity and mortality.[49]

Pathogenesis

Microorganisms gain access into the lower respiratory tract via aspiration of oropharyngeal pathogens and leakage of secretions around the endotracheal tube cuff in intubated patients.[84],[85] Invasive-care devices, contaminated equipment, and transfer of microorganisms among staff and patients serve as the primary pathogen sources,[86] and although more controversial, the gastrointestinal tract may also play a role in bacterial colonization.[87]

Clinical Presentation and Diagnosis

HAP and VAP are all diagnosed on the basis of radiographic findings, clinical features, and health care setting when there is initial evidence of infection. Patients must demonstrate new or progressive infiltrates on imaging as well as two of three of the following signs: fever greater than 38°C, leukopenia or leukocytosis, and purulent sputum. Patients will often experience declines in oxygen saturation, but this finding is less specific for determining the need for empiric antimicrobial agents.[88]

Respiratory cultures may be taken from endotracheal aspirates, bronchoalveolar lavage, or protected-specimen brush samples. Blood cultures lack sensitivity, and when positive, consideration should also be given to a potential extrapulmonary source.[89]

Overview of Treatment

The IDSA/ATS have published guidelines for the treatment of HAP. [49] The five major principles underlying the management of HAP and VAP include the following: (a) failure to initiate prompt, appropriate therapy is associated with increased mortality; (b) the variability of bacteriology from one institution to another, as well as within specific sites in a hospital, can be significant; (c) the overuse of antibiotics should be avoided by focusing on accurate diagnosis; (d) therapy should be tailored based on lower respiratory tract cultures and the duration of therapy should be shortened; and (e) prevention strategies directed at modifiable risk factors should be applied. The likelihood of an infection with a potential pathogen is based largely on the time to onset of HAP, severity of the condition, and underlying risk factors. In general, patients with early-onset disease who are not severely ill and have no risk factors for MDR organisms can be treated with a single agent including a non-antipseudomonal third-generation cephalosporin or an antipneumococcal fluoroquinolone (Table 67-8). Empiric therapy in those with late-onset or severe disease should include a combination of antibiotics active against Pseudomonas. This regimen usually includes an antipseudomonal β-lactam, such as cefepime, imipenem, meropenem, doripenem, or piperacillin-tazobactam, plus either an aminoglycoside or ciprofloxacin/levofloxacin. Vancomycin or linezolid should be added if MRSA risk factors are present or there is a high institutional incidence (Table 67-9).[49]

Microbiology

The major difference in the bacteriology between CAP and HAP, HCAP, or VAP is a shift to gram-negative pathogens, MDR pathogens, and MRSA. Gram-negative bacilli commonly colonize oropharyngeal secretions of patients with moderate-to-severe (acute and chronic) diseases without exposure to broad-spectrum antibiotics.[90] Patients admitted to the hospital with acute illnesses are rapidly colonized with gram-negative organisms. Approximately 20% are colonized on the first hospital day, and this number increases with the duration of hospitalization and severity of illness. Approximately 35% to 45% of hospitalized patients and up to 100% of critically ill patients will be colonized within 3 to 5 days of admission.[90],[91]

In the past, gram-negative bacteria accounted for 50% to 70% of all cases of HAP and VAP[49],[92–96]; however, gram-positive organisms have become increasingly common, with S. aureus responsible for upward of 40% of cases of HAP and VAP. This is in stark contrast to CAP bacteriology, in which S. aureus represents 25% or less of cases. P. aeruginosa remains the most prevalent gram-negative organism in HAP and VAP, accounting for approximately 20% to 25% of infections. [97] In patients who are ventilator dependent, Acinetobacter species is an increasingly common gram-negative pathogen. Other organisms with special risk factors include Legionella, which is associated with high-dose corticosteroid use and outbreaks secondary to water supplies and cooling systems,[91],[98] and Aspergillus, which is associated with neutropenia or organ transplantation.[99]

Risk factors for MDR pathogens include patient-specific factors such as antimicrobial therapy in the previous 90 days, current hospitalization of 5 days or more, and immunosuppressive disease or therapy. Coverage for MDR organisms should also be initiated if there is a high frequency of community, hospital, or health care facility (i.e., nursing home) antibiotic resistance.[100]

CASE 67-5

QUESTION 1: M.L. is a 71-year-old man admitted to the hospital for a deep vein thrombosis. His past medical history is significant for chronic kidney disease (CrCl 40 mL/minute), diabetes mellitus, COPD, GERD, hypertension, and a recent diagnosis of non–small cell lung cancer for which he is not currently receiving chemotherapy. M.L.'s home medications include lisinopril, famotidine, aspirin, insulin glargine, insulin aspart, tiotropium, fluticasone/salmeterol, and as-needed albuterol. What characteristics does M.L. exhibit that place him at risk for HAP?

Table 67-8

Empiric Therapy for Hospital-Acquired Pneumonia and Ventilator-Associated

Pneumonia in Patients with No Known Risk Factors for Multidrug Resistant Pathogens and Onset <5 Days

Possible Pathogens	Recommended Therapy	Dosage
Streptococcus pneumoniae[a] Haemophilus influenza MSSA Antibiotic-sensitive enteric GNB Escherichia coli Klebsiella pneumonia Enterobacter sp. Proteus sp. Serratia marcescens	Ceftriaxone	1–2 g IV every 24 hours
	Or	
	Levofloxacin	750 mg IV every 24 hours
	Or	
	Moxifloxacin	400 mg IV every 24 hours
	Or	
	Ertapenem	1 g IV q24 hours
	Or	
	Ampicillin-sulbactam	3 g IV q6 hours

[a] The frequency of penicillin-resistant S. pneumoniae and multidrug-resistant S. pneumoniae is increasing; levofloxacin or moxifloxacin are preferred to ciprofloxacin.

GNB, gram-negative bacilli; IV, intravenous; MSSA, methicillin-sensitive Staphylococcus aureus.

Table 67-9

Empiric Therapy for Hospital-Acquired Pneumonia and Ventilator-Associated Pneumonia in Patients with Late-Onset Infection (≥5 days) or Risk Factors for Multidrug Resistant Pathogens

Possible Pathogens	Recommended Combination Therapy	Adult Dosage[a]
MDR pathogens	Antipseudomonal cephalosporin	
Pseudomonas aeruginosa	Cefepime	1–2 g IV every 8–12 hours
	Ceftazidime	2 g IV every 8 hours
Klebsiella pneumoniae (ESBL+)[b]	Or	
Acinetobacter sp.[b]	Antipseudomonal carbapenem	
	Imipenem–cilastatin	500 mg IV every 6 hours or 1 g IV every 8 hours
	Doripenem	500 mg IV every 6–8 hours[c]
	Meropenem	1 g IV every 8 hours
	Or	
	β-Lactam/β-Lactamase inhibitor	
	Piperacillin–tazobactam	3.375–4.5 g IV every 8 hours (infused over 4 hours)
	Plus	
	Antipseudomonal fluoroquinolone[d]	
	Ciprofloxacin	400 mg IV every 8 hours
	Or	
	Levofloxacin	
	Or	

	Aminoglycoside Amikacin Gentamicin Tobramycin	750 mg IV every 24 hours 15–20 mg/kg IV every 24 hours[e] 5–7 mg/kg IV every 24 hours[e] 5–7 mg/kg IV every 24 hours[e]
MRSA[d]	Plus Vancomycin Or Linezolid	15 mg/kg every 12 hours 600 mg every 12 hours[f]
Legionella pneumophila[g]	Azithromycin	500 mg IV every 24 hours

[a] Dosages are based on normal renal and hepatic function.

[b] If an ESBL+ strain, such as K. pneumoniae, or an Acinetobacter sp. is suspected, a carbapenem is a reliable choice.

[c] Studied infusion times range from 30 minutes to 4 hours.

[d] If MRSA risk factors are present, or there is a high incidence locally.

[e] Trough levels for gentamicin and tobramycin should be <1 mcg/mL; for amikacin, they should be <4–5 mcg/mL.

[f] Trough levels for vancomycin should be 15–20 mcg/mL.

[g] If L. pneumophila is suspected, a combination antibiotic regimen including a macrolide (e.g., azithromycin) or a fluoroquinolone (e.g., ciprofloxacin or levofloxacin) should be used.

ESBL, extended-spectrum β-lactamase; IV, intravenous; MDR, multidrug-resistant; MRSA, methicillin-resistant Staphylococcus aureus.

Source: Management of Adults With Hospital-acquired and Ventilator-associated Pneumonia: 2016 Clinical Practice Guidelines by the Infectious Diseases Society of America and the American Thoracic Society. Clin Inf Dis. 2016;63;1–51.

Several risk factors for HAP have been identified, including intubation and mechanical ventilation, aspiration, a patient’s body position, the administration of enteral feeding, prior use of antibacterial agents, gastrointestinal bleeding prophylaxis (i.e., histamine type 2 antagonists and proton-pump inhibitors), immunosuppressive therapy, and poor nutrition status or glucose control. Other nonmodifiable risk factors associated with developing HAP include age older than 70 years and chronic lung disease.

An important factor in the cause of pneumonia is colonization of the oropharynx, common in alcoholism and with prolonged hospitalization, and previous antimicrobial exposure.[49] Several factors may contribute to the colonization of M.L.’s oropharynx with gram-negative bacteria. In addition to his pulmonary disease, an altered immune response in diabetics and the elderly can predispose M.L. to respiratory infection. The use of drugs that inhibit the production of gastric acid, such as famotidine and omeprazole, increases the possibility of oropharyngeal colonization and pneumonia; yet acid suppressive medications are commonly used to prevent gastric stress ulcers in mechanically ventilated patients.[101–104]

Antibiotic Therapy

CASE 67-5, QUESTION 2: Three days after admission, while receiving anticoagulation for the deep vein thrombosis, M.L. exhibits a fever to 39.3°C. Antibiotics were inappropriately delayed, and over the next 24 hours, his respiratory function declined significantly requiring intubation (Pao_2/FIO_2 250). Additionally, objective findings showed elevated WBC count (17,200 cells/μL), left shift (immature leukocytes, bands 18%), and a new infiltrate on his daily chest radiograph. Sputum cultures are sent, and the decision is made to start M.L. on antibiotics. How should antimicrobial therapy be managed for M.L.?

Because delays in the administration of appropriate therapy have been associated with increased hospital mortality from HAP, the prompt administration of empiric therapy is essential. Importantly, changing therapy once culture results are available may not reduce the excess risk of hospital mortality if inappropriate initial therapy is selected.[49] To this end, local bacteriologic patterns and in vitro susceptibility data should be made available and updated

as frequently as possible to allow for appropriate selection of initial empirical therapy. In addition to the selection of an appropriate agent, the selection of adequate dosing regimens will optimize the pharmacodynamic properties of the antibacterial agent(s) and improve clinical outcomes and mortality rates.[49]

Resolution of HAP can be defined both clinically and microbiologically. Clinical improvement usually is apparent after the first 48 to 72 hours of therapy. During this time, the selected antibacterial regimen should not be changed unless progressive deterioration takes place or microbiologic studies confirm the pathogen.

If culture results are negative or inconclusive (because of known specimen contamination with mouth flora), the patient's response to the initial antibiotic therapy should be used to evaluate modification of the antibiotic regimen. If the patient responds to the initial regimen, consideration should be given to narrowing coverage to the most likely causative pathogens.

If the patient is not responding to the initial antibiotic therapy, one should consider whether (a) the pathogen is not covered in the initial choice of antibiotic therapy, (b) the dose of antibiotic is insufficient, and (c) any other factors are responsible for the failure to respond to therapy. Such factors include poor pulmonary clearance of necrotic tissue and cellular debris, lung abscesses or empyema, and severely altered host defenses leading to a rapidly fatal underlying disease.

Of note, if one of the following organisms is isolated (Serratia, Pseudomonas, indole-positive Proteus, Citrobacter, or Enterobacter species), in vitro reports indicating susceptibility should be carefully evaluated, as these organisms often possess an inducible β-lactamase gene (also referred to as a type I β-lactamase enzyme).[105] In vitro testing may demonstrate susceptibility to third-generation cephalosporins and extended-spectrum penicillins, but this may not translate into efficacy in the clinical setting. As a possible scenario of infection with these organisms, after initiation with one of the above agents, the patient may initially respond; however, after approximately 1 week, the patient's condition begins to worsen. Because treatment with the β-lactam agent induces the expression of the type I enzyme, a subsequent sputum specimen sent after approximately 1 week is now likely to demonstrate resistance to the third-generation cephalosporins and extended-spectrum penicillins.[105] Although cefepime is more likely to be active against these isolates, a large inoculum of organisms (e.g., that present in pneumonia) can result in β-lactamase degradation of this agent as well.[106] Considering that this phenomenon will not be identified by using usual in vitro testing, cefepime should be used cautiously in these patients.[107] The preferred therapy in these patients includes trimethoprim–sulfamethoxazole, a fluoroquinolone, or a carbapenem.[105] Acinetobacter species are increasingly resistant to many commonly used antibacterial agents. Treatment of this often multiply-resistant pathogen requires the use of very high doses of ampicillin–sulbactam (up to 24 g/day) or colistin.[108],[109]

CASE 67-5, QUESTION 3: Seventy-two hours after empiric antibiotics were initiated, the microbiology laboratory reports that greater than 100,000 colonies/mL of MRSA have grown on M.L.'s sputum culture. Antibiotics are de-escalated to vancomycin therapy alone, to which the isolate is susceptible. After a loading dose and aggressive maintenance regimen, vancomycin trough concentrations have been 17 to 22 mcg/mL. However, M.L. remains febrile, demonstrates progression of his infiltrates on chest radiograph, and has acute worsening of renal function requiring dialysis and necessitating vancomycin dose adjustment. Repeat tracheal cultures again grow only S. aureus with susceptibility to vancomycin, sulfamethoxazole–trimethoprim, daptomycin, and linezolid. Should M.L.'s antibiotic therapy be modified?

The first IDSA MRSA infection treatment guidelines[110] were published in 2011 and are discussed subsequently in collaboration with the first vancomycin therapeutic monitoring guidelines jointly developed by the American Society of Health-System Pharmacists, the Society of Infectious Diseases Pharmacists, and the IDSA.[111]

For MRSA pneumonia, IV vancomycin, or linezolid 600 mg by mouth (PO) or IV twice daily, or clindamycin 600 mg PO or IV 3 times daily (if the strain is susceptible) is recommended for 7 to 21 days, depending on the extent of infection. Daptomycin should not be used for the treatment of MRSA pneumonia, because its activity is inhibited by pulmonary surfactant, rendering it inactive in the treatment of lung infection.[110]

VANCOMYCIN

The recommended dosing of IV vancomycin is 15 to 20 mg/kg/dose (actual body weight) every 8 to 12 hours, not to exceed 2 g/dose, for patients with normal renal function. A loading dose of 25 to 30 mg/kg (actual body weight) may be considered. Some patients may experience an adverse event during the infusion of vancomycin known as red man syndrome. Extending the infusion time to 2 hours for larger doses or premedicating patients who have experienced this phenomenon with an antihistamine may alleviate this adverse event.[110]

Vancomycin trough concentrations of 15 to 20 mcg/mL are recommended for the treatment of pneumonia[110] as higher trough serum concentrations should increase the likelihood of optimizing the area under the curve (AUC) and minimum inhibitory concentration (MIC) and, therefore, take into account higher vancomycin MIC values appreciated in some isolates. It has also been postulated that targeting higher trough values may help to overcome vancomycin's inherent impaired penetration into epithelial lining fluid and respiratory secretions.[111] Of note, there are no data confirming that achievement of more aggressive trough levels is associated with improvement in clinical cure.[112]

LINEZOLID

Linezolid achieves higher concentrations in lung epithelial fluid than in plasma[113] and serves as an alternative to vancomycin for the treatment of MRSA pneumonia. A retrospective analysis of two prospective trials[114],[115] for the treatment of HAP found that patients in the subgroup of MRSA cases randomly assigned to linezolid experienced higher cure rates and lower mortality compared with vancomycin.[116] In contrast, a meta-analysis of eight randomized control trials comparing glycopeptide antibiotics to linezolid for suspected MRSA pneumonia found no evidence to support superiority of linezolid.[117] The ZEPHyR study compared linezolid with vancomycin in patients with proven nosocomial MRSA pneumonia in a randomized, double-blind fashion. This is the largest trial conducted in this population to date, and it showed a statistical improvement with linezolid in clinical outcomes at the end of study; yet the confidence interval was close to no significance and only showed a benefit with linezolid in identified nosocomial MRSA pneumonia.[118] These results make it difficult for initial selection over vancomycin for empiric therapy of MRSA coverage. Therefore, it remains uncertain whether linezolid or vancomycin should be considered superior.

M.L. is at risk for MDR pathogens (current hospitalization of 5 days or more and immunosuppressive diseases) and should be started empirically with an anti-MRSA agent (vancomycin), and double coverage for resistant gram-negative pathogens (cefepime and gentamicin or ciprofloxacin). (Table 67-9) Dosing and frequency of antimicrobial agents will require renal adjustments because of M.L.'s chronic renal issues. When culture results are known, the antibiotic regimen can be modified and individualized. For patients with uncomplicated HAP or VAP, who have received appropriate empiric antibiotics with a satisfactory subsequent

---

clinical response, 7 to 10 days of therapy is recommended.[49] However, patients infected with nonfermenting gram-negative bacilli (i.e., pseudomonas and acinetobacter) may benefit from longer courses (14 days or greater) to prevent recurrence.[119] M.L.'s clinical response should be monitored to determine whether the selected antibiotics are effective in treating this infection. These parameters include the ability to discontinue mechanical intubation and decreases in temperature and WBC count with resolution of the left shift.

Since M.L. remains febrile despite MRSA sensitivities to vancomycin with appropriate trough concentrations, it is appropriate to consider alternative MRSA coverage. Despite MRSA susceptibility to daptomycin, the drug does not penetrate lung surfactant, and therefore it is not appropriate to use in the treatment of pneumonia. Sulfamethoxazole–trimethoprim is a less appealing option owing to the patient's dialysis requirement. M.L. should be switched to linezolid. Linezolid quickly reaches high lung concentrations and is safe to use in the setting of acute renal failure. Linezolid has been associated with thrombocytopenia and neutropenia. Platelet counts and WBC should be monitored at baseline and at least every 7 days during treatment.

ALTERNATIVE AGENTS

Doxycycline, clindamycin, and sulfamethoxazole–trimethoprim are not reliably active against MRSA strains, and recent research has focused on novel agents. Although active against MRSA, tigecycline has been associated with worsened clinical outcomes when used for the treatment of HAP, including MRSA pneumonia.[120] Telavancin has been compared with vancomycin in the treatment of HAP caused by gram-positive pathogens. Treatment with telavancin achieved higher clinical cure rates in patients with monomicrobial S. aureus infection and in those with isolates that demonstrated a vancomycin MIC of at least 1 mcg/mL. However, lower cure rates were observed in the telavancin group in those who had mixed infections. Telavancin use was also associated with a higher incidence in serum creatinine elevation; yet the drug was approved by the US Food and Drug Administration in 2013 for HAP when other alternatives are not suitable.[121]

AMINOGLYCOSIDES

Individualization of aminoglycoside dosing is imperative as the therapeutic outcome (efficacy and toxicity) of aminoglycosides correlates with plasma concentrations in patients with gram-negative pneumonia.[122–125] In patients receiving multiple daily doses of gentamicin or tobramycin and achieving a 1-hour postinfusion peak plasma concentration of greater than 7 mcg/mL, a successful outcome occurs more often than in those with lower plasma concentrations.

The aminoglycosides are concentration-dependent killing antibiotics. The rate and extent of killing organisms is maximized by increasing their peak serum concentration relative to the MIC of the pathogen. In addition to maximizing bactericidal activity, in vitro evidence has demonstrated that this concentration goal also minimizes the development of resistance. The use of once-daily dosing strategies to minimize nephrotoxicity of the aminoglycosides has been studied extensively. Single doses of gentamicin and tobramycin (5–7 mg/kg/day) and of amikacin (15–20 mg/kg/day) have been reported to be as effective as standard dosing (smaller single doses given every 8 or every 12 hours) of these agents in controlled clinical trials. However, none of the trials has enrolled a sufficient number of patients required to demonstrate a lower incidence of nephrotoxicity. There are several advantages of once-daily dose aminoglycoside therapy: (a) it is no more nephrotoxic than traditional dosing, (b) clinicians are ensured that a therapeutic peak serum level will be achieved with the first dose, (c) it is the only safe and effective way to achieve serum peak levels of 10 to 20 times the MIC for difficult-to-treat organisms such as P. aeruginosa, and (d) it is a more efficient dosing regimen (fewer doses and administration times per day; fewer serum level measurements are required).[49]

Despite the use of individualized aminoglycoside dosing, morbidity and mortality rates attributable to gram-negative pneumonia remain high. This is because the success of antibiotic therapy depends on the ability of the antibiotic to reach the site of infection and remain biologically active.[125] Concentrations of the aminoglycosides in bronchial secretions range from 1 to 5 mcg/mL (30%–40% of serum concentrations) 2 to 4 hours after parenteral administration.[126],[127] These concentrations may be insufficient to inhibit the growth of many gram-negative organisms, especially Pseudomonas.

Lastly, aminoglycosides bind to purulent exudates and cellular debris and are inactivated by these agents.[128–130] In summary, the aminoglycosides penetrate poorly into bronchial secretions and are less active at the site of infection because of local pH effects and binding to cellular debris. These properties may result in the need for increased dosages, placing patients at increased risk for ototoxicity and nephrotoxicity. Therefore, unless no reasonable alternative exists, aminoglycoside monotherapy for the treatment of pneumonia should be avoided.

INHALED AGENTS FOR MULTIDRUG-RESISTANT PATHOGENS

Because of the growing incidence of pneumonia caused by MDR gram-negative organisms, interest has been renewed in the use of inhaled aminoglycosides and polymyxin products. When given systemically, both classes have been associated with poor pulmonary penetration and with nephrotoxicity, with polymyxin carrying the additional risk of neurotoxicity, and with aminoglycosides ototoxicity. However, the proposed high drug concentrations at the site of pulmonary infection, minimal systemic exposure after nebulized administration, and data showing benefit in both the prevention and treatment of Pseudomonas pulmonary infection in cystic fibrosis patients make aerosolized antibiotic therapy an appealing strategy for the treatment of VAP. The IDSA/ATS guidelines state that aerosolized antimicrobials may be considered in patients with MDR organisms not responding well to IV therapy.[49]
